1.0 Executive Summary:

1. Barren-ground caribou herds across North America have undergone large changes in numbers over time for hundreds and likely thousands of years, based on scientific studies and knowledge of aboriginal elders. Variation in weather and forage quality and quantity on the calving and summer ranges are probably major factors affecting population trend in most barren-ground caribou herds, but the relationships are complex. Population trend and environmental trends may vary in neighbouring herds, thus each herd has individual circumstances. A large part of the Bathurst herd's decline since 1986 is likely the result of this natural "cycle" as it parallels similar trends in other NWT/Nunavut herds, and more widely in migratory caribou/reindeer herds across the global north.
2. There is no evidence that a significant proportion of Bathurst caribou cows switched to either of the neighbouring Bluenose-East or Ahiak ranges, given the satellite collar data for the three herds, steep decline in cow numbers on the Ahiak calving grounds 2006-2009, and likely continued decline in the Bluenose-East herd. These conclusions would be stronger with greater collar numbers on the Bathurst herd and a new population estimate for the Bluenose-East herd. Low rates of exchange between collared cows on neighbouring calving grounds, as in these three herds, are consistent with results from Alaska, Labrador/Quebec, and other herds in NWT and Nunavut.
3. Like other barren-ground caribou herds in the NWT, the Bathurst herd would most likely have declined in the early 2000s regardless of harvest, with a later peak of calving and low spring calf:cow ratios consistent with a declining herd from 2000 to 2006. Conditions for at least two other NWT herds (Bluenose-West and Cape Bathurst) were similar in these years, as evidenced by late calving and reduced June calf:cow ratios.
4. The overall pattern of decline followed by faster decline at lower herd size was similar in the Cape Bathurst, Bluenose-West and Bathurst herds. In the Cape Bathurst and Bluenose-West herds, estimated harvest rates in 2005 were high and unsustainable and included primarily cows. The switch from rapid decline to apparent stability from 2006 to 2009 in both herds followed harvest closure in the Cape Bathurst herd and harvest reduction (4% harvest with 80% bulls) in the Bluenose-West herd. These changes suggest that harvest had contributed significantly to decline in these herds, particularly at low numbers, and could have limited recovery if the harvest had not been restricted.
5. The aboriginal harvest of the Bathurst herd is not well documented but GNWT records of harvest by outfitters, resident hunters, check-station data and model analyses suggest that a total harvest of about 4000-5000 cows/year and about 2,000 bulls/year is a reasonable estimate of annual harvest in recent years. Unlike earlier periods of low caribou numbers, the hunter harvest likely did not decline as the herd decreased, aided by easy access on winter roads to the communities and mines in the Bathurst range. A harvest of 5000 cows would have been 2.4% of the herd's 210,300 adult cows in 1996, but it would be 21.7% of the herd's estimated 23,060 cows in June 2009. A lower harvest estimate of 3000 cows would be 13.0% of the herd's cows in June 2009.
6. The recovery of the Bathurst herd would require a substantial increase in cow survival and good calf survival, with good fecundity. There is no level of calf recruitment that can compensate for current estimated cow survival rates of 67-68% (mortality rate of 32-33%). If current cow survival rates, calf survival rates and fecundity continue unchanged, the herd could be lost or may reach extremely low numbers in 4-5 years. The smaller the herd becomes, the longer the expected period of recovery. Although bull harvest has less impact on caribou population trend than cow harvest, skewing the sex ratio strongly towards low bull:cow ratios should be avoided because of potential effects on population genetics, the importance of prime bulls to migration, and the value of breeding by prime bulls to temporally concentrated calving.

7. At a cow survival rate of 86%, calf survival would need to be 50-53% in the Bathurst herd to result in a stable herd, based on population modeling. At a cow survival rate of 91%, calf survival of 32-35% would be needed for a stable herd. These estimates are model projections, but they are similar to published estimates in other barren-ground caribou herds. Under optimal conditions, with no harvest, the Bathurst herd might stabilize and begin a modest increase in about 5 years. However, environmental trends, individual survival and normal year-to-year variation will occur in the real world, thus all model projections are indicators of likely trend under a particular set of assumptions, not predictions.
8. Poor recruitment in the early 2000s contributed substantially to the herd's decline in those years. Combined with higher recruitment in 2007-2009, this has led to an age structure with a slightly increased representation of older cows, a substantial representation of very young cows, and somewhat fewer middle-aged cows. In other caribou herds this kind of shift in age structure has contributed to declines if the older cows had lower productivity or survival rates. Given the very high cow mortality rates, good condition and high pregnancy rates in the Bathurst herd, this has probably not been a significant factor in the Bathurst decline. The high proportion of very young cows could slow the herd's recovery initially as these females may need another year or two to contribute young to the herd.
9. Although barren-ground caribou herds have been known to fluctuate in numbers over a wide range, they may sometimes remain at low numbers for extended periods. At very low numbers, predator-prey relationships may change, with the advantages of gregarious and temporally concentrated calving ("swamping" predators) largely lost. This may be affecting the potential recovery of the Beverly herd, which is at very low numbers, with documented high cow mortality rates, low calf:cow ratios and limited evidence of cows switching to the calving grounds of the more numerous Ahik herd. This is an example of the risks of a barren-ground caribou herd reaching very low numbers.
10. Environmental trends in the Bathurst range in recent years have included increasing temperatures and increases in precipitation, but less precipitation as snow. The plant growing season has grown longer and plant biomass has increased, but forage quality has shown a slow declining trend. Snowmelt on the calving ground was annually variable; 1998 and 2008 were two early years, and 2001 and 2005 were two late years. There has been a reduction in lichen-rich habitats on the winter range, largely as a result of forest fires. High pregnancy rates, good body condition in Bathurst cows 2007-2009, and higher spring calf:cow ratios than in the early 2000s suggest that environmental conditions for Bathurst caribou in 2007-2009 were improved over the early 2000s.
11. Although information on wolf and bear numbers in the Bathurst range is incomplete, annual surveys of wolf dens at the southern end of the Bathurst summer range since 1996 suggest that wolf numbers and productivity have fallen rapidly in recent years as the caribou herd has declined. With few alternate prey to sustain them, wolves decline in numbers as their prey declines. This typically manifests itself through low pup survival and recruitment. Observations of wolves and bears on the Bathurst calving grounds have been limited. In about 14,000 km of survey flight lines on or near the Bathurst calving ground in June 2009, there were 8 bear sightings and 4 wolf sightings.
12. The diamond mines in the Bathurst summer range have resulted in reduced use by caribou around the mines, to a distance of 14 km. This effect has been relatively small at the scale of the herd, with about 4% of the summer range affected by reduced use. Caribou may have also had increased energy costs (more time spent running or walking, less time feeding) if they were near the mines, but this effect has been small, in part because caribou have avoided the mines. Overall, effects of the mines to date have been limited and are unlikely to have been a major contributing factor in the rapid Bathurst decline from 2006 to 2009. To date the largest effect of the mines is likely greater access for hunters on the additional winter roads.

3.0 Introduction (JA)

A June 2009 survey on the Bathurst caribou herd's calving ground produced an estimate of $16,600 \pm 4,500$ breeding females (rounded estimate $\pm 95\%$ confidence interval) and a population estimate of $31,900 \pm 10,900$, a decline of 70% in 3 years (Figure 3.1). This herd had declined slowly in the 1990s but its rate of decline increased as the herd reached lower numbers. The accelerated decline and the importance of this herd to NWT communities led to a number of analyses, workshops and plans for management actions to allow the herd to recover. The Wek'èezhii Renewable Resources Board (WRRB) asked for a joint management proposal for the Bathurst herd from the Tlicho (TG) and Northwest Territories (GNWT) governments by the end of October 2009. Because the Bathurst range is large (ca. 350,000 km², Figure 3.2) and takes in portions of Nunavut, NWT and Saskatchewan, management of the herd must include several jurisdictions and all communities that hunt this herd.

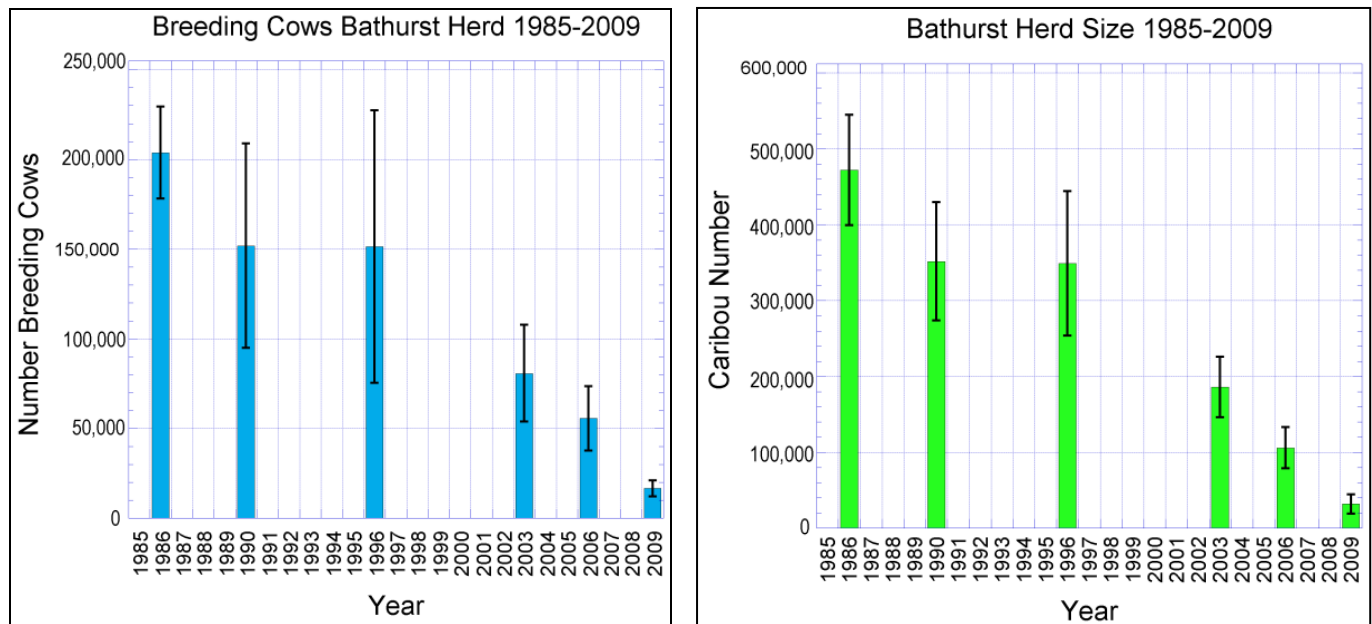

Figure 3.1. Estimated number of breeding females (left) and population size (right) of the Bathurst Caribou Herd, 1985-2009. All six estimates are based on calving ground photo-surveys. Error bars are 95% confidence intervals.

As a companion to the management proposal to the WRRB, biologists with the GNWT will also submit this technical report on the Bathurst decline. A technical meeting was held in Calgary on Sept. 26 and 27, 2009 to review the information and follow-up analyses carried out by statistician and modeler John Boulanger in summer and fall 2009. In addition, a non-technical report on two workshop sessions on the Bathurst decline in Yellowknife on Oct. 1 and 2, and Oct. 5 and 6, 2009 was prepared by Nesbitt and Adamczewski (2009). A number of graphs and images are common to the technical and non-technical reports. Detailed analyses and methods are included as supporting documents to the technical report. To ensure that the report is sound and interpretations of the data are valid, GNWT asked Don Russell (semi-retired caribou biologist) and Jason Fisher (Alberta Research Council) to attend the September meeting in Calgary and to review a draft of this report as they would review a manuscript submitted to a journal for peer-review.

The objectives of this report are:

- 1) To review information on the Bathurst herd decline, with emphasis on the recent accelerated decline. This includes field observations as well as associated modeling outcomes;
- 2) To evaluate possible explanations for the accelerated decline; and
- 3) To evaluate the herd's prospects for recovery, using population models and studies of other caribou herds.

This report is a collaboration among the authors. Individual sections written primarily by one or more authors are identified by the person's initials at the beginning of the section.

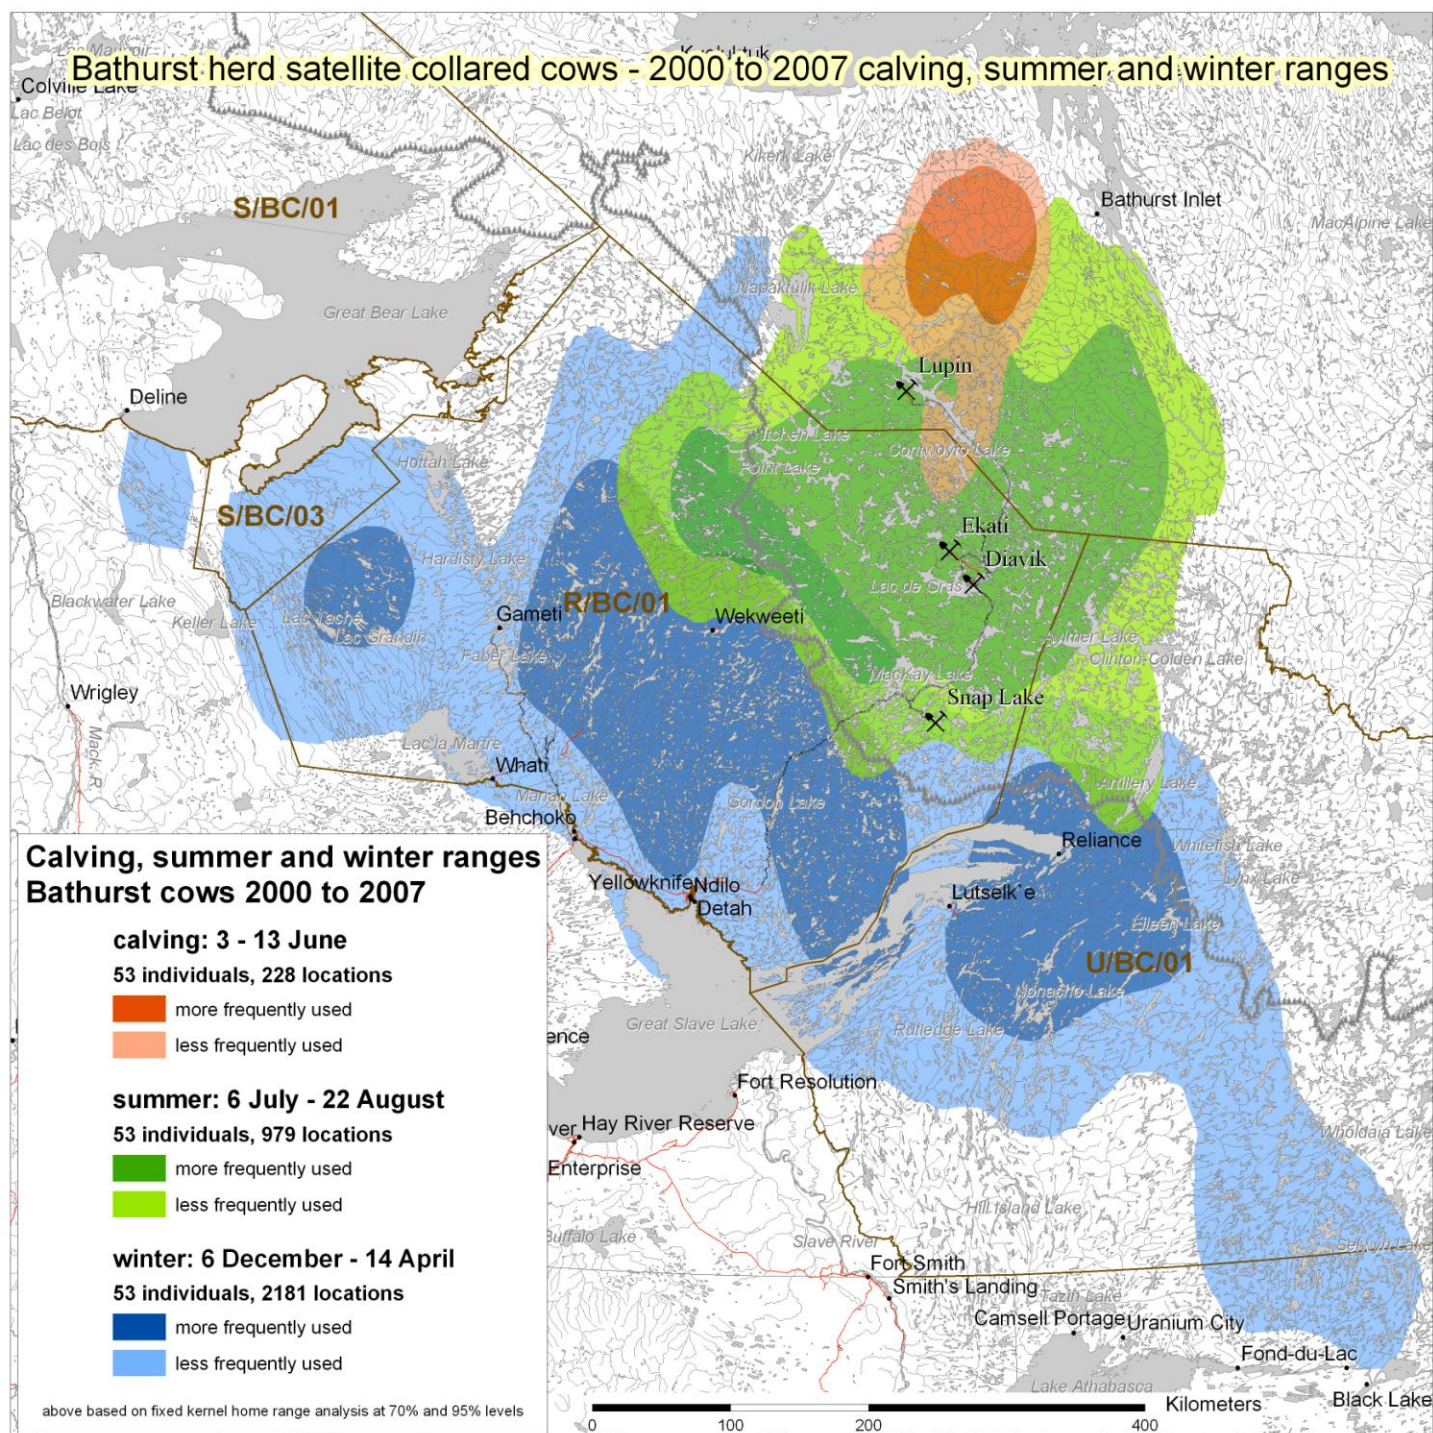

Figure 3.2. Calving, summer and winter ranges of the Bathurst caribou herd. Seasonal ranges are identified based on satellite collar locations of cows from 2000 to 2007. Outer polygons are based on 95% kernel contours and the inner ones are based on 70% contours. Winter roads to Gameti, Wekweeti and the active diamond mines at Ekati, Diavik and Snap Lake provide access during winter. Mapped by Adrian D'Hont, ENR

3.1 Management context for the Bathurst caribou herd

Management of the Bathurst caribou herd must take into account the size of the herd's range and the jurisdictions that share this herd. The herd's calving ground is in Nunavut and has been southwest of Bathurst Inlet since 1996 (Gunn et al. 2008a). The summer range is partially in Nunavut and partially in the NWT, much of the fall and winter range is in the NWT, and a portion of the herd has been found south of the 60th parallel in Saskatchewan in some winters (Figure 3.2). Within the NWT, a portion of the herd's summer, fall and winter range lies with the Tlicho Settlement Area, a land claim area within which the Tlicho government has authority over Tlicho lands. The Wek'èezhii Renewable Resources Board has responsibility for wildlife decision-making in the Tlicho settlement area. The GNWT has responsibilities throughout the NWT; because other aboriginal groups also hunt the Bathurst herd, GNWT must consult with them on any issues affecting harvesting rights. The Bathurst herd is hunted by more communities than any other in the NWT. The four Tlicho communities (Behchokö, Whatì, Wekweetì, Gamètì) are within the herd's winter range. Hunters from Yellowknife, Dettah, N'Dilo and communities south of Great Slave Lake also hunt the Bathurst herd. In recent winters, access to caribou has increased by winter roads to the Tlicho communities Whatì, Wekweetì, and Gamètì, and roads to mines at Discovery, Diavik, Ekati, and Snap Lake.

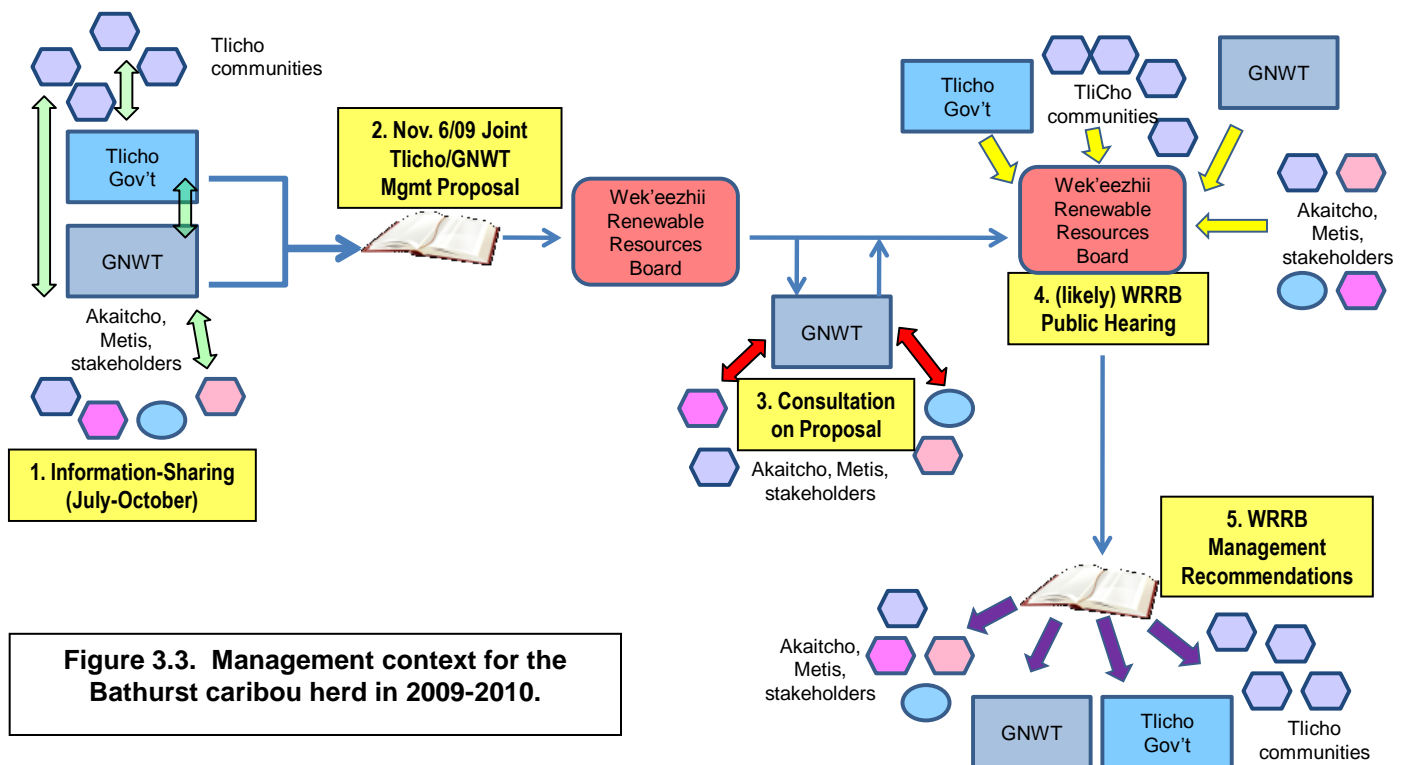

Figure 3.3. Management context for the Bathurst caribou herd in 2009-2010.

Figure 3.3 identifies a sequence of actions that will result in management recommendations for the Bathurst caribou herd. Proposed management may also affect the herds east and west of the Bathurst herd (Ahiak and Bluenose-East)

1. Development of management actions for the Bathurst herd began with information-sharing meetings and workshops in summer and fall 2009 (Figure 3.3).
2. The WRRB asked for a joint management proposal from the Tlicho government and GNWT by Oct. 30, 2009.
3. GNWT will consult on the proposal with other groups and aboriginal governments, some of whom do not have settled land claims.

4. The WRRB will most likely call for a formal hearing on Total Allowable Harvest for the Bathurst herd in early 2010, and any concerned communities and groups may make presentations as intervenors at these hearings.
5. The WRRB will then make management recommendations for the herd's management. These dates are approximate and may change.

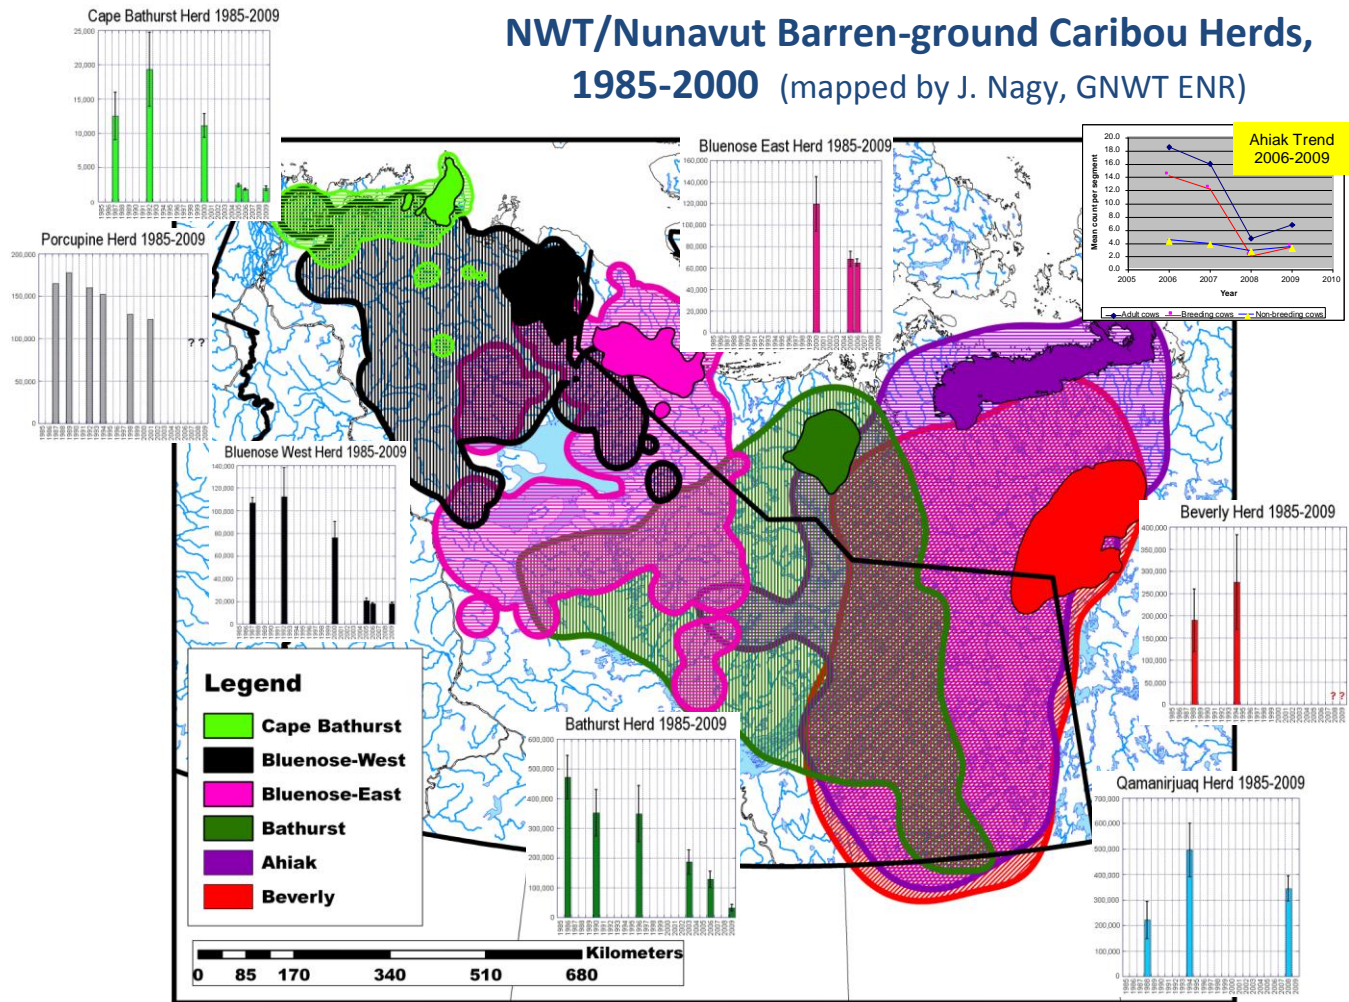

Figure 3.4. Annual ranges and population status of barren-ground caribou herds monitored by GNWT biologists, 1985-2009. The Porcupine and Qamanirjuaq herds are monitored by Alaska/Yukon biologists and by Government of Nunavut, respectively.

3.2 Status of NWT/Nunavut Barren-ground Caribou Herds Monitored by GNWT in 2009

Barren-ground caribou herds in the NWT and Nunavut are defined based on calving grounds to which breeding females return annually in June. The same approach is used throughout North America where these herds occur (Gunn and Miller 1986, Valkenburg et al. 2003, Gunn et al. 2008a). Biologists with the GNWT monitor several of these herds (Figure 3.4). Each annual range on the map is based on an accumulation of locations from satellite collared cows over time, using the 95% kernel contour to draw the outside boundary. The calving ground for each herd is shown as a solid block at the north end of the annual range, and is likewise based on satellite collared cow locations. All the herds shown in Figure 3.4 declined over the period 1985 to 2008, some more rapidly than others.

The Porcupine herd's range is not shown on the map. It is found to the east of the mapped area, in northern Yukon and Alaska. This herd was estimated at 178,000 in 1989 and then declined at a gradual rate through the 1990s and 2000s (survey information from web-site of the Porcupine Caribou Management Board <http://www.taiga.net/pcmb>). Alaskan biologists have used post-calving photo surveys for this herd, but since 2001 have been unable to complete one of these surveys because of weather problems. These surveys can provide population estimates with high precision (Valkenburg et al. 1985, Rivest et al. 1998, Rettie 2008) but they require relatively large numbers of satellite collars (Rivest et al. 1998, Rettie 2008) and they rely on the caribou forming dense aggregations of hundreds or thousands in response to insect harassment in July. These groups can be photographed and counted. Caribou may not aggregate sufficiently in cooler or windier weather, preventing photography and a population estimate. Post-calving surveys were attempted on the Porcupine herd annually from 2003 to 2009 but failed due to unsuitable weather. A population model used for this herd suggests that the herd numbered about 90,000 in 2009; the Porcupine herd has been well monitored (calf:cow ratios, cow survival estimation, harvest data, etc) so biologists are confident in the model projection.

The Cape Bathurst herd is one of the smaller barren-ground caribou herds in the NWT. It was estimated at $19,300 \pm 5,400$ in 1992, then declined to about $11,100 \pm 1,800$ in 2000 and just $2,430 \pm 260$ in July 2005 (Nagy and Johnson 2006). Because the 2005 survey of this herd showed such a steep decline in 5 years, it was repeated in 2006 and the decline was confirmed with an even lower estimate ($1,820 \pm 150$; Nagy and Johnson 2006). The preliminary estimate for a July 2009 survey of this herd is $1,930 \pm 350$ (T. Davison, ENR Inuvik Region, pers. comm. Oct. 2009).

Figure 3.5. Post-calving photo surveys used on the Cape Bathurst, Bluenose-West and Bluenose-East herds. Groups of caribou are photographed from a small aircraft, and caribou are counted digitally. A high proportion of caribou (>90%) are found in groups with at least one satellite collar. Large groups usually have several collars.

The Bluenose-West herd is the Cape Bathurst herd's eastern neighbor and showed a similar population trend over the same period. From a peak herd size estimated at over $112,400 \pm 25,600$ in 1992, this herd declined to about $76,400 \pm 14,300$ in 2000, then declined at a higher rate to $20,800 \pm 2,040$ in 2005 (Nagy and Johnson 2006). The low result in 2005 was confirmed a year later with a repeated post-calving survey and an estimate of $18,050 \pm 530$ caribou (Nagy and Johnson 2006). The preliminary estimate for a July 2009 survey of this herd is $17,900 \pm 1,300$ (T. Davison, ENR Inuvik Region, pers. comm. Oct. 2009). The Cape Bathurst and Bluenose-West herds were in 2009 the only herds in Fig. 3.4 with a stable trend; all other herds showed a declining trend.

Population estimates for the Cape Bathurst and Bluenose-West herds from 2000 on are based on individual surveys for each herd. Previous post-calving surveys of the Bluenose herd in 1986, 1987 and 1992 were

based on a single “Bluenose” herd. Population estimates for these two herds prior to 2000 are based on re-analyses of the earlier combined Bluenose herds, as described by Nagy (2009b).

Population estimates for the Bluenose-East herd were not available before 2000, when this herd was estimated at $119,600 \pm 25,400$ (Nagy et al. 2008). Like its western neighbours, this herd declined steeply to an estimated $70,100 \pm 8,100$ in 2005 and $66,800 \pm 5,200$ in 2006 (Nagy and Tracz 2006, Nagy et al. 2008). The 2006 survey and estimate were repetitions of the survey and estimate a year earlier. A post-calving survey was attempted for this herd in July 2009, but failed because of cool weather and insufficient aggregation by caribou.

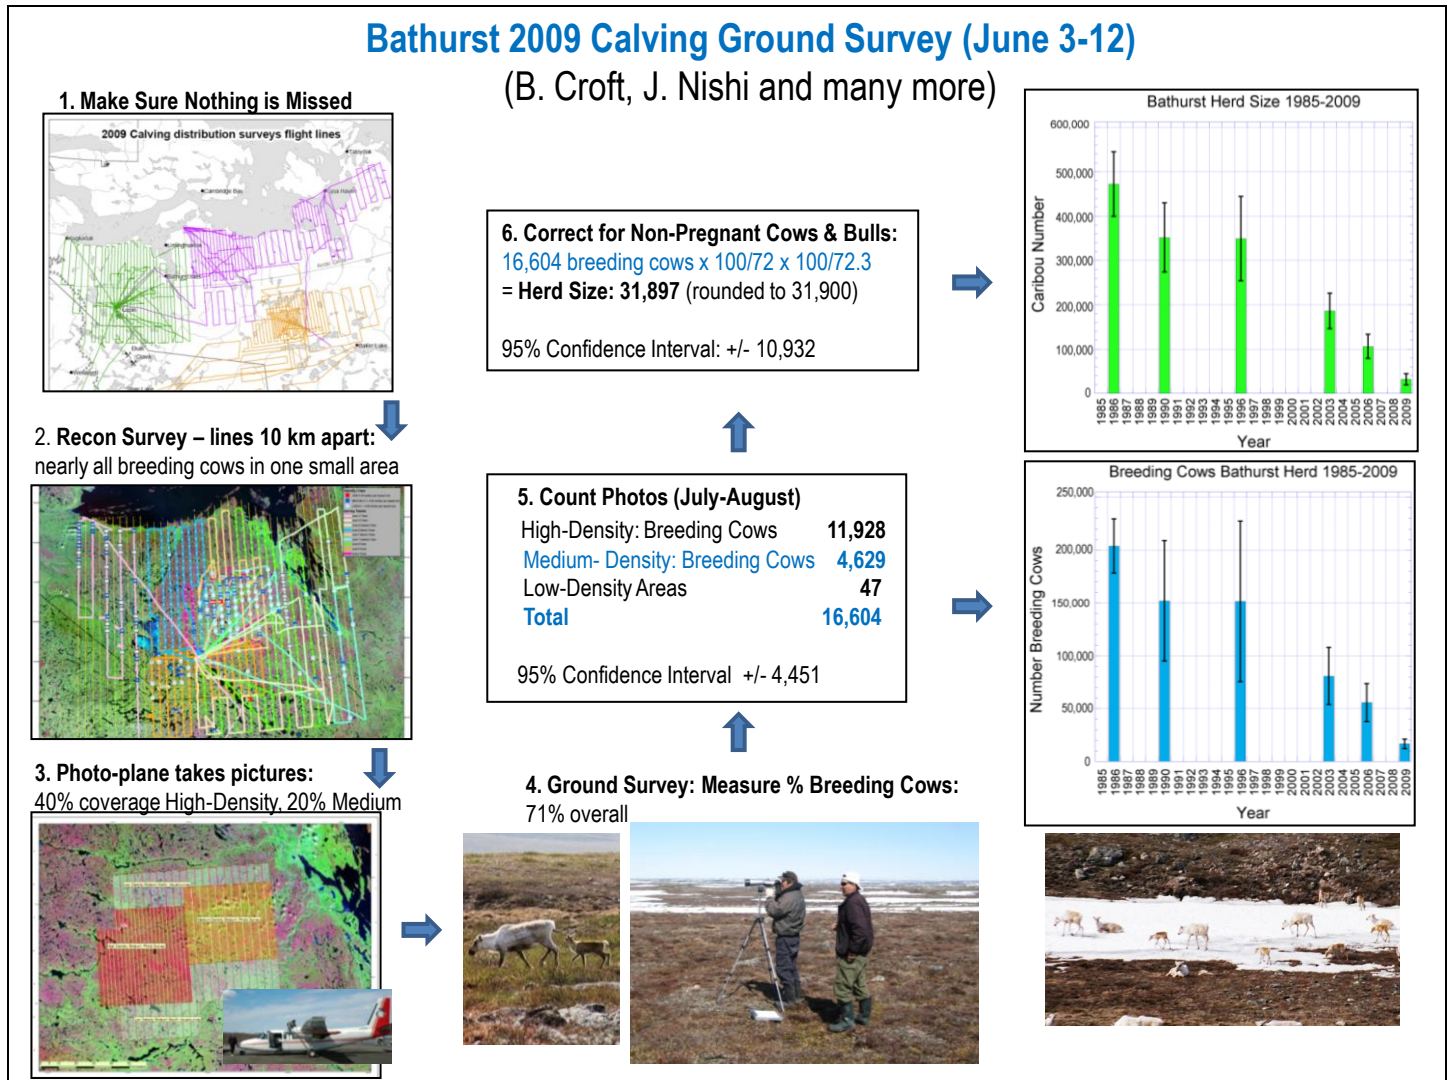

Figure 3.6. Key steps in the June 2009 Bathurst calving ground photo survey. Reconnaissance flight lines covered an area much larger than the actual calving ground, spanned Bathurst Inlet to the western end of the Ahik calving ground, and spanned an area to the west where the Bluenose-East calving ground would begin. The photo-plane took photos over 40% of the high-density area and 20% of the medium-density area. Less than 2% of the cows were counted visually on low-density areas. Extrapolation to overall herd size used a fall 2008 sex ratio of 38 bulls:100 cows.

The Bathurst herd was estimated at $472,000 \pm 72,900$ in 1986, was stable or declined slowly through the 1990s and then at a higher rate in the 2000s (Gunn et al. 2008a). The June 2009 calving photos survey resulted in an estimate of $31,900 \pm 10,900$, a decline of 70% in 3 years. Key steps in the calving photo survey in June 2009 are in Figure 3.6.

To the east of the Bathurst range, the Ahiak herd has had generally less monitoring than other NWT herds, in part due to its remote range and in part because it is rarely accessible to NWT hunters. In recent years satellite collars show that cows that calve on this elongated east-west calving ground south of the Queen Maud Gulf have a long north-south migration that takes some cows as far south as Saskatchewan. Preliminary analysis of satellite collar locations by J. Nagy shows that collared cows that use the more easterly end of the Queen Maud Gulf area are tundra-wintering and have a pattern of movement distinct from that of the cows using the more westerly portion of the Queen Maud Gulf. A population survey of the caribou in the Queen Maud Gulf area (the first) is planned as a cooperative effort between Nunavut and NWT biologists for June 2010. Figure 3.4 includes a graph showing the average number of cows seen per 10-km transect on calving reconnaissance surveys from 2006 to 2009; these show a strong downward trend over this 4-year period (see Section 4.2).

The calving ground shown for the Beverly herd in Figure 3.4 is based on the traditional calving ground defined by the Beverly and Qamanirjuaq Caribou Management Board, which was defined from previous surveys rather than satellite collar locations. Satellite collared collar locations for Beverly cows are limited, in part because community approval for satellite collars on this herd was not secured until 2006. In addition, calving reconnaissance surveys in 2002, 2007, 2008 and 2009 have documented a decline of about 99% in numbers of caribou cows using this calving ground in June. The most rapid decline occurred between 2002 and 2007. Satellite collar locations of cows known to use the Beverly calving ground in June indicate that a few have switched from the Beverly to the Ahiak calving grounds, and outside of the calving period, the Beverly satellite collared cows do not appear to have distinct seasonal ranges. Mortality rates of the few Beverly collared cows in 2006-2009 have been exceptionally high. In June 2008, the calf:cow ratio near the peak of calving was 15:100, where calf:cow ratios would normally be 70-90: 100 at this time of year. As a result, the Beverly range shown in Figure 3.4 is nearly the same as the Ahiak range. This is an exceptional situation with (to our knowledge) no precedent in Canadian technical studies of barren-ground caribou.

3.3 Calving and Post-Calving Surveys of Barren-ground Caribou in the NWT

GNWT biologists have used post-calving photo surveys for the more western barren-ground caribou herds (Cape Bathurst, Bluenose-West and Bluenose-East) and calving photo surveys for the more eastern herds (Bathurst and Beverly) since the 1980s. Nunavut government biologists have used calving ground photo surveys for the Qamanirjuaq herd. Both methods have some advantages and some disadvantages.

Post-calving photo surveys provide estimates of total herd size as cows and bulls are counted. These surveys require relatively large numbers of satellite collars because the collars are the primary cue to locations of caribou groups. A few additional groups of caribou without collars are usually found near groups that have collars, but usually well over 90% of the caribou found are in large groups with one or more collars. Re-analysis of 2006 GNWT post-calving surveys by Rettie (2008) suggested that satellite collar numbers for the Cape Bathurst, Bluenose-West and Bluenose-East surveys were sufficient in 2006, and he suggested that 2009 surveys of these herds should use 30, 60 and 40-60 collars, respectively, for these three herds. These recommendations were met or exceeded for all three herds in 2009. Post-calving surveys can provide population estimates with high precision, where nearly every adult caribou in the herd is counted from photographs (Valkenburg et al. 1985, Rettie 2008, Nagy 2009a). However, photography may not be possible if the weather does not lead to dense aggregations of caribou, as in the Bluenose-East herd in 2009 and the Porcupine herd 2003-2009. In addition, larger numbers of satellite collars are expensive to purchase, deploy and acquire locations from. There has been continuing opposition to the use of satellite collars in some northern aboriginal communities, based on concerns over the effects of the collars on caribou and concerns that handling animals is disrespectful to them. As a result, there have never been more than 20 satellite collars on the Bathurst herd and approval for satellite collars on the Beverly herd was not obtained in Nunavut until 2006. A defensible post-calving survey of the Bathurst herd would not be feasible with less than 20 collars.

Calving ground photo-surveys in the NWT estimate the number of breeding cows on the calving grounds. These surveys have generally been less vulnerable to weather, although the photo-plane does require 1-2 days of good weather in June as it flies at about 2000 feet. In the 1980s calving ground photo-surveys were done on the eastern Canadian herds with no satellite collars, as the reliability of breeding cows returning to calving grounds was high. However, exceptional spring weather may delay cows from reaching their normal calving grounds. In 2001 the Porcupine caribou cows calved far south of their usual coastal calving grounds (Griffith et al. 2002) and very few cows were on the normal calving grounds that June. Satellite collars allowed biologists to monitor the herd's movements and the unusual calving patterns that year. Without satellite collars a calving ground with fewer caribou than expected might be difficult to interpret. On Bathurst calving photo-surveys in the 1990s and 2000s, even the relatively low numbers of satellite collars used (10-20) provided some assurance that most of the herd's cows were part of the survey, as a high proportion during every June survey were in the higher-density areas on the calving grounds. Because some of the non-pregnant cows and nearly all the bulls are not on the calving grounds, an extrapolation to overall herd size is needed (see Section 5.1 for calculations). Some biologists are not comfortable with this extrapolation (Thomas 1998) and it does tend to increase the variance or confidence interval around the population estimate.

A direct comparison of the post-calving and calving photo surveys has only been carried out once, with paired surveys of the George River herd in Quebec/Labrador in 1994 (Couturier et al. 1996). The population estimates in that case were very similar, providing some confidence that the two survey methods were fundamentally sound.

3.4 Barren-ground Caribou: global status and population cycles

On a global scale, caribou and reindeer across their range in North America, Russia and Alaska show a largely declining trend in 2009 (Vors and Boyce 2009; Figure 3.7). Of 58 caribou and reindeer populations, 34 were reported as declining, 8 were increasing, and for 16 there were no data (Vors and Boyce 2009). A few of the populations in Fig. 3.7 are boreal woodland caribou in Canada and summations of multiple herds in Newfoundland, Norway and Sweden. The ecology of Scandinavian reindeer and Newfoundland caribou, with essentially no wolves, differs from that of most Canadian migratory caribou herds. However, most of the larger Russian, Alaskan and Canadian migratory caribou and reindeer herds were declining, even though monitoring, management of caribou and management of predators differ widely across this vast northern landscape. Vors and Boyce (2009) suggested that climate change and weather patterns are most likely the main drivers in the current declines. Generalization about caribou and reindeer herds must be done with caution, though, as there are exceptions, and conditions for individual herds may be unique. In Quebec/Labrador, the George River herd has been declining since the early 1990s, but its neighbor the Leaf River herd has increased over the same period (Bergerud et al. 2008). In Alaska the Porcupine and Western Arctic herds are declining while the Central Arctic and Teshekpuk herds are increasing. Overall, however, the declining trend in barren-ground caribou herds in NWT and Nunavut is consistent with a strong trend toward declines in migratory caribou and reindeer across their range in Canada, Alaska, Russia and Scandinavia.

Traditional Knowledge of aboriginal people in the NWT and studies by biologists both have demonstrated that barren-ground caribou have fluctuated widely over time, going back hundreds and possibly thousands of years. A re-construction of a cycle in caribou numbers from D. Beaulieu's family and Chipewyan elders shows peaks and troughs every 30 years (Figure 3.8). The peaks occurred in years when caribou were very numerous near Rocher River (southwest of Great Slave Lake, near the Taltson River). During the low periods in caribou numbers, hunters from Rocher River had to travel long distances to find caribou. Although the peaks have occurred on a 30-year interval, successive peaks have been lower and lower, possibly due to increased hunting and cumulative effects of development.

Long-time caribou biologist Tom Bergerud re-constructed a 200-year history for the George River herd in Quebec/Labrador from a number of sources (Figure 3.9). Some of the information was from Innu and Inuit oral history, including records of hunting at river crossings where people traditionally hunted caribou, and periods

when people starved. In addition, biologists used scars on black spruce tree roots from caribou migration trails (Morneau and Payette 2000), calibrated against known population size for the George River herd from aerial surveys 1960-2000. The re-construction shows that population highs were sometimes separated by prolonged low periods, intervals between lows and highs varied in length, and successive peaks and lows sometimes fell increasingly lower.

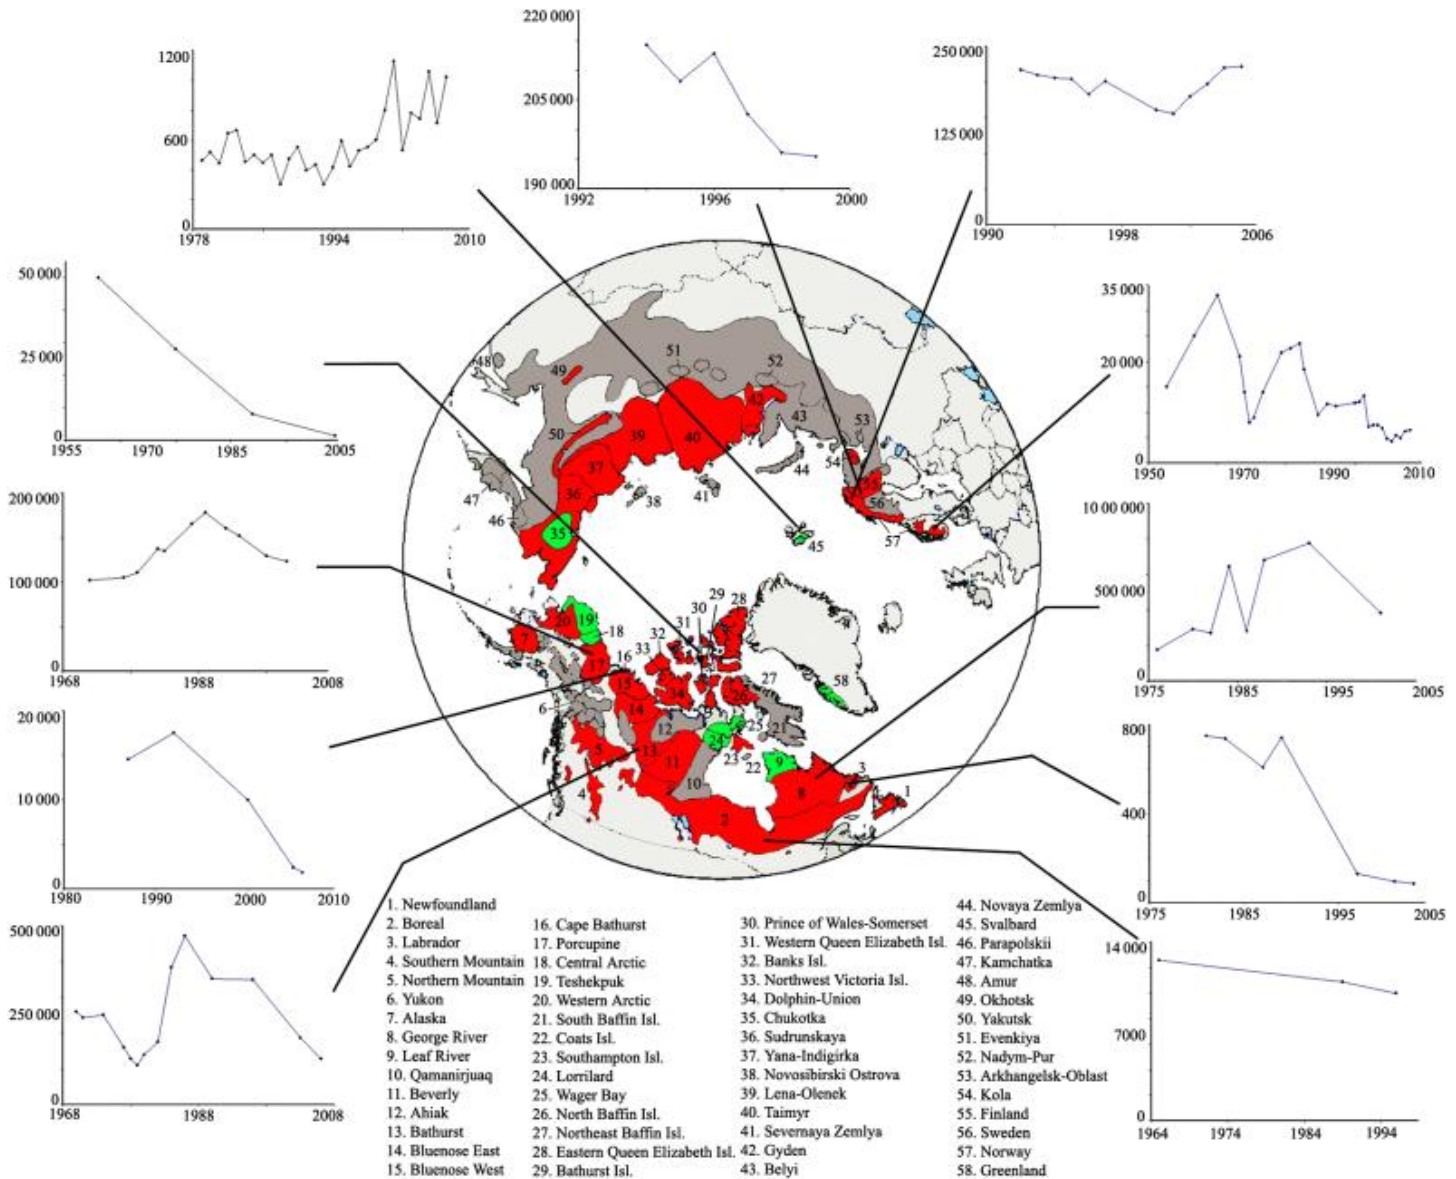

Fig. 3.7 Population trajectories of 58 major caribou and reindeer herds worldwide. Herd ranges depicted in red are in population decline and ranges depicted in green are experiencing population growth. Population data are unavailable for herd ranges illustrated in grey. Time series of population estimates for 11 caribou and reindeer populations are included to illustrate historical fluctuations in population size. The x-axis represents year of population estimate and the y-axis represents estimate of population size.

(From Vors and Boyce. 2009. Global declines of caribou and reindeer, *Global Change Biology* 15: 2626-2633)

In an application of the spruce root scar method pioneered in the George River herd's range, Zalatan et al. (2006) compared spruce root scars and Tlicho elders' knowledge of Bathurst caribou abundance over a period from 1920 to 1980 (Figure 3.10). The spruce root scars and Tlicho elders' knowledge agreed on a peak in

caribou numbers in the 1940's. The spruce scars picked up the decline in the 1990s recorded from population surveys, but suggested that the population peak may have occurred a few years before the peak population estimate from aerial surveys.

Figure 3.8. (From D. Beaulieu, ENR, Yellowknife) Cycles in caribou numbers over time based on Traditional Knowledge of Chipewyan elders and several generations of D. Beaulieu's family.

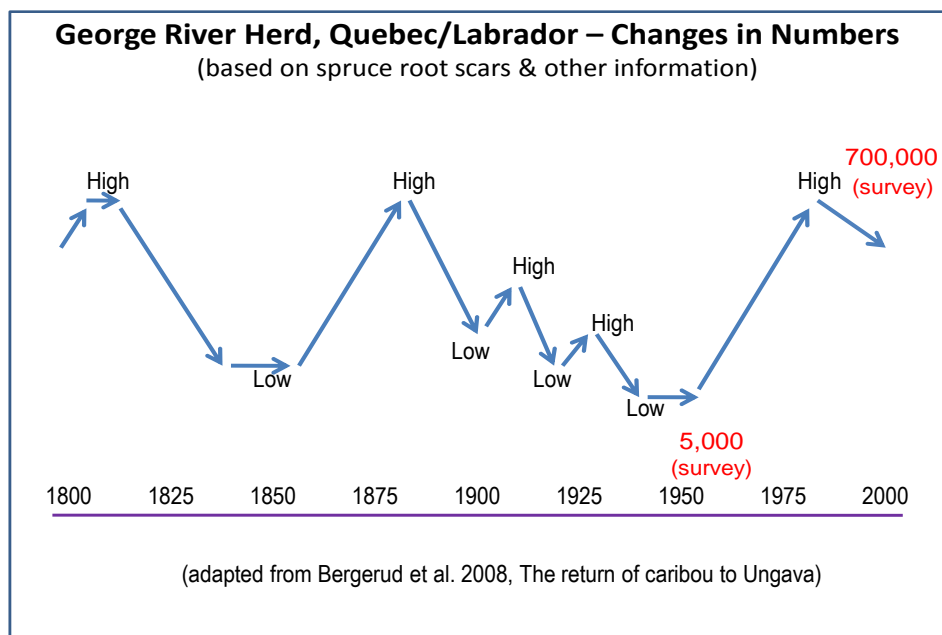

Figure 3.9. A 200-year re-construction of abundance in the George River herd in Quebec/Labrador. Adapted from Bergerud, A. T., S. N. Luttich, and L. Camps. 2008. The return of caribou to Ungava. McGill-Queen's University Press, Montreal and Kingston, Ontario.

In summary, the declining trend of the Bathurst herd, like those of other herds in NWT/Nunavut, is consistent with a global declining trend in most migratory caribou and reindeer herds. Large increases and decreases in numbers of Bathurst caribou and other herds have occurred in the past, based on Traditional Knowledge, spruce root scars on caribou migration trails, and in the last 40 years, from aerial surveys. These fluctuations

are most likely driven by weather at a large scale, although the relationships are complex (Gunn 2003). Variation among neighboring herds has occurred, though, including sometimes opposite trends, thus explanations for declines in particular herds must consider each herd's individual conditions.

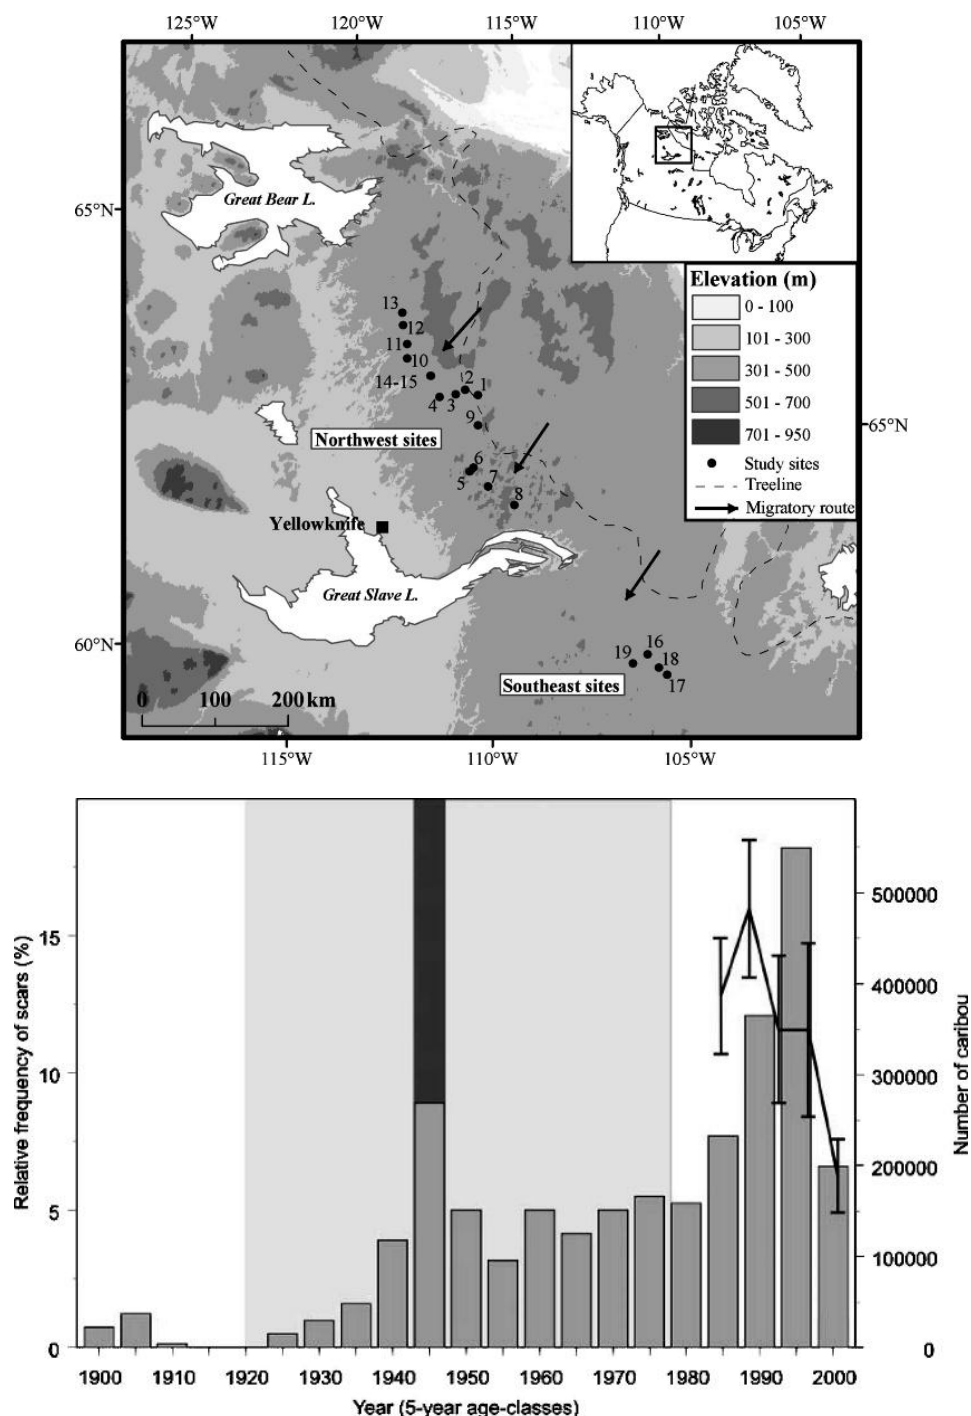

Figure 3.10. Locations of sampling sites in the summer/fall ranges of the Bathurst herd (top) and spruce root scar frequency by year for the period 1900-2000 (bottom). The light grey period from 1920 to 1980 is the period over which Tlicho elders provided their knowledge of Bathurst caribou abundance. From Zalatan, Gunn, and Henry. 2006: Long-term abundance patterns of barren-ground caribou using trampling scars on roots of *Picea mariana* in the Northwest Territories, Canada. *Arctic, Antarctic and Alpine Research* 38(4): 624-630.

4.0 Likelihood of large-scale emigration from the Bathurst herd (JB & AK)

When biologists report that a caribou herd has declined, a question that is often asked is whether the missing caribou could have gone somewhere else. We addressed this question for the Bathurst decline by looking at satellite collar movements between the Bathurst herd and its neighbours to the east (Ahiak herd) and west (Bluenose-East herd), by evaluating population trend in these neighbouring herds, and by a brief review of the published literature of rates of switching among neighbouring barren-ground caribou herds. A brief review of caribou surveys flown in 2007, 2008 and 2009 indicates that there is little likelihood of the “missing” Bathurst caribou having been overlooked.

4.1 Satellite collar movements between herds

Collared caribou from the Bathurst, Ahiak, and Bluenose-East herd have been monitored since the late 1990s, and monitoring included tracking the calving grounds that they used. Bull caribou have been satellite collared in the Bluenose-East herd (also in the Bluenose-West and Cape Bathurst herds), but most collars have been on cows and only data from cows are considered here. We used this data set to assess the rate of movements between calving grounds for the Bathurst, Ahiak, and Bluenose-East caribou herds. Although the satellite collars are used for various purposes by biologists and managers, they are not specifically intended to measure emigration or immigration. In mammals, emigration (and therefore immigration) most often occurs in juveniles, especially young males. A full discussion of emigration is beyond the scope of this report. However, adult cows almost invariably make up well over half of a barren-ground caribou herd and they are a high proportion of the caribou found on the calving ground in June. If the reduction in numbers of breeding cows on the Bathurst calving ground is to be explained, then the cows are the appropriate segment of the herd to investigate. We should expect some of the satellite collared cows to switch ranges if a substantial proportion of the herd’s cows switch ranges.

To build the data set for the analyses, Adrian D’Hont (ENR) classified each collared caribou from the Bathurst, Ahiak, and Bluenose-East herds in terms of which calving ground they occupied each year. The resulting data set contained 153 caribou. The actual number of caribou tracked varied yearly and by herd as shown in Figure 4.1.

Figure 4.1: Yearly sample sizes of adult cow collared caribou used in the multi-strata analysis, from the Ahiak, Bathurst and Bluenose-East herds.

Of the 153 caribou, 4 occurred on both the Ahiak and Bathurst calving grounds in subsequent years, and 3 occurred on both the Bathurst and Bluenose-East calving grounds (4.5 % of the total). In other words, 95.5% of the collared cows used only one calving ground in the time period monitored. No caribou occurred on both the Bluenose-East and Ahiak calving grounds.

We were further interested to determine if there was net movement between calving grounds, or if movement between calving grounds was random and non-directional so it could be assumed that the rate of movement from a calving ground (emigration) was equal to the rate of movement into a calving ground (immigration).

It is important to note that the caribou used in this analysis were mostly young or middle-aged cows and were not collared on the calving grounds. Because of the fidelity of collared cows to calving grounds, we believe most of these cows were born on the same calving grounds. Assessing life-long fidelity of caribou cows to calving grounds would require tracking them from birth through adult life. This analysis is limited to estimating yearly rates of movement between calving grounds. In addition, we assume similar rates of movement between age classes given that no age-class data were available to estimate age-specific yearly movement rates.

The question of movement between populations or areas has been addressed extensively as part of mark-recapture analyses of other wildlife species. In particular, multi-strata models (Hestbeck et al. 1991, Brownie et al. 1993) estimate emigration and immigration rates from different areas, which in the case of barren-ground caribou are calving ground grounds. Data for a multi-strata model are entered as a yearly encounter history with a caribou defined by the calving ground it was observed on in June that year. For example, if caribou # 100 was seen in the Bathurst herd calving ground in 2000 but on the Ahiak in 2001, was not detected in 2002, and then detected in 2002 on the Bathurst calving ground, then the data in the model would be entered as BA0B, where B denotes Bathurst herd and A denotes Ahiak herd and 0 denotes not observed. The model then uses this sequence to estimate the probability that a caribou that is on the Bathurst calving ground one year will be on the Ahiak calving ground the following year, and vice versa. This is analogous to estimating emigration/immigration rates between herds.

Multi strata models estimate rates of movement (termed transition probabilities) between calving grounds, yearly survival, and recapture rate. Yearly survival was not of interest in this analysis and we assumed that capture probability was 1. Namely, a caribou that had a collar had a probability of detection of 1 on the calving ground. Assumptions about herd-specific survival can affect movement estimates and so we considered models that considered herd-specific and pooled survival rates. As part of program MARK (White and Burnham 1999), it was also possible to constrain multi-strata models to test particular hypotheses about movement between calving grounds. In particular, we were interested in knowing whether there was net emigration from the Bathurst calving ground. If emigration rates from the Bathurst herd were distinctly different (larger) than immigration rates, then we would expect that the net collar movement away from the Bathurst calving ground would be greater than the immigration rate. There was no documented movement between the Ahiak and Bluenose-East herds and therefore movement rates between these two herds were fixed at 0.

The fit of models was evaluated using the Akaike Information Criterion (AIC) index of model fit. The model with the lowest AICc score was considered the most parsimonious, thus minimizing estimate bias and optimizing precision (Burnham and Anderson 1998). The difference in AICc values between the most supported model and other models ($\Delta AICc$) was also used to evaluate the fit of models when their AICc scores were close. In general, any model with a $\Delta AICc$ score of less than 2 was worthy of consideration or plausible.

Model selection result suggested there was no detectable difference between emigration and immigration rates for the Bathurst-Ahiak or Bathurst-Bluenose-East (Table 4.1, model 1). A model that assumed similar emigration rates of caribou from the Bathurst to the Bluenose-East and Ahiak herds, and equal immigration from the Ahiak and Bluenose-East herds to the Bathurst herd, was also marginally supported (Model 2).

Table 4.1: Model selection results for multi-strata model analysis of movements between the Ahiak, Bathurst, and Bluenose-East herds. Sample-size adjusted Akaike Information Criteria (AICc), difference in AICc between most supported and given model ($\Delta AICc$), Akaike weight (w_i), the number of parameters (K), effective sample size (ESS), and deviance (an index of model fit) are given. Movement rates were estimated for the Bathurst-Ahiak and Bathurst-Bluenose-East, but not the Bluenose-East-Ahiak. Herds are symbolized by Bathurst (B), Ahiak(A), and Bluenose-East (E). Movement rates are symbolized by the ordering of herds. For example BA symbolizes movements from the Bathurst to the Ahiak.

Model No.	Survival	Movement	AICc	$\Delta AICc$	w_i	K	Deviance
1	pooled	BA=BE=EB=AB	10127.9	0.00	0.48	2	9810.7
2	pooled	BA=BE, EB=AB	10130.0	2.01	0.18	3	9810.7
3	herd	BA=BE=EB=AB	10131.0	3.10	0.10	4	9809.7
4	pooled	BA=BE,EB,AB	10131.1	3.12	0.10	4	9809.7
5	pooled	BA,BE, EB=AB	10131.8	3.86	0.07	4	9810.5
6	pooled	BA=BE, EB=AB	10132.9	4.98	0.04	5	9809.5
7	pooled	BA, BE, EB,AB	10134.2	6.27	0.02	6	9808.7

These results are best interpreted by looking at model-averaged estimates of movement which suggested that both emigration and immigration rates were 0.03 for the Bathurst herd to the Bluenose-East and Ahiak calving grounds (Figure 4.2).

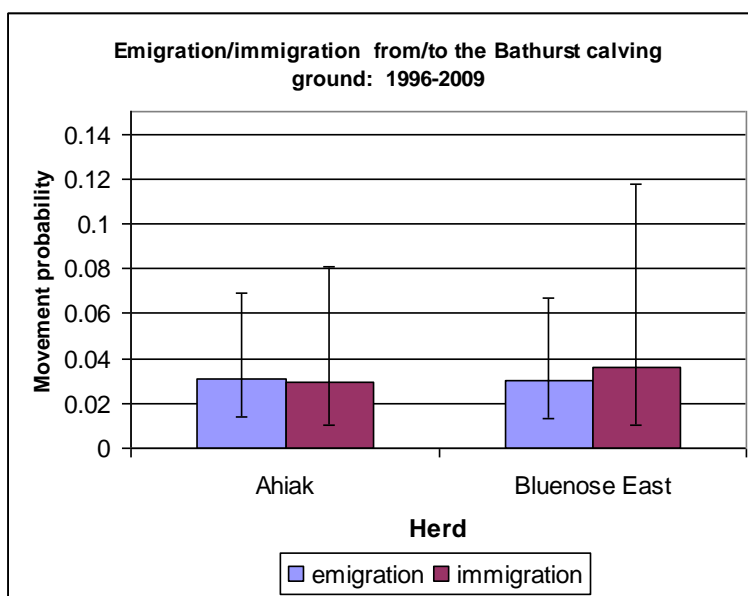

Figure 4.2. Model averaged estimates of emigration from the Bathurst calving ground and immigration to the Bathurst calving ground from the Ahiak and Bluenose-East calving grounds, 1996-2009.

Model averaged estimates suggest that emigration and immigration rates were low and similar, especially when the confidence limits on the estimates are considered. These estimates should be interpreted as the probability that a caribou on the Bathurst calving ground would emigrate or switch to the Ahiak (emigrate) or the probability that a caribou on the Ahiak calving ground would switch (immigrate) to the Bathurst calving ground. These results suggest there was no detectable net movement of caribou to or from the Bathurst herd calving ground to the Ahiak or Bluenose-East calving grounds.

We also evaluated whether movements between these 3 herds may have been greater in the past 3 years (rapid Bathurst decline) than in earlier years. During this 3-year period, there were more collared caribou in the Ahiak and Bluenose-East herds but the Bathurst collar numbers changed little. We therefore did an analysis that only considered data from 2006 to 2009. This analysis included 101 caribou. Of these, 2 were observed on both the Bathurst and Bluenose-East calving grounds, and 4 were observed on the Bathurst and Ahiak calving grounds. In other words, 94% of the cows were recorded on only one calving ground.

For this analysis a model that suggested similar emigration rates of caribou from the Bathurst to other herds, and similar immigration rates into the Bathurst from other herds was most supported. This model was tied in terms of support (as indicated by $\Delta AICc$ values of less than 2) with a model that assumed that immigration equaled emigration (model 2), and a model that had unique emigration rates from the Bathurst but equal immigration rates (model 3).

Table 4.2: Model selection results for multi-strata model analysis of movements between the Ahiak, Bathurst, and Bluenose-East herds 2006-2009. Sample-size adjusted Akaike Information Criteria (AICc), difference in AICc between most supported and given model ($\Delta AICc$), Akaike weight (w_i), the number of parameters (K), effective sample size (ESS), and deviance (an index of model fit) are given. Herds are abbreviated as Bathurst (B), Ahiak(A) and Bluenose-East (E). Movement is denoted by order of herd abbreviations. For example, BE denotes movement of Bathurst to Bluenose-East and EB denotes movement of Bluenose-East to Bathurst.

Model No.	survival	movement	AICc	$\Delta AICc$	w_i	K	Deviance
1	pooled	BA=BE, EB=AB	7185.32	0.00	0.318	3	6959.8

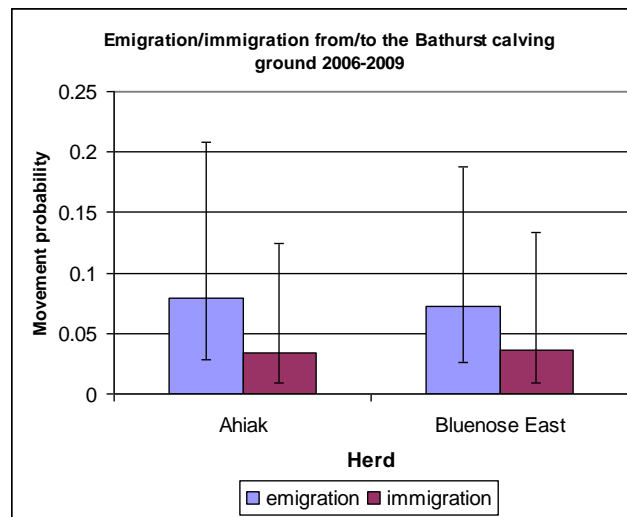

Figure 4.3: Model averaged estimates of emigration from the Bathurst herd and immigration into the Bathurst herd calving ground from the Ahiak and Bluenose-East caribou herds from 2006 to 2009.

Inspection of model-average estimates suggests that emigration rates were slightly higher than immigration rates. However, overall immigration and emigration rates were relatively low (Figure 4.3). From a statistical point of view, it is not possible to conclude that emigration rates do not equal immigration rates given the overlap of confidence intervals of the immigration and emigration rates, and the support of model 2 which assumes equal immigration and emigration rates.

In conclusion, data from collared caribou demonstrate there was some yearly movement between calving grounds with overall rates being low. Analysis of recent data suggests emigration rates are slightly higher than immigration rates, however, this difference is not statistically significant. Results from this analysis should be treated cautiously given the lower sample sizes of collared caribou used for estimates.

4.2 Population trend in the Ahiak Herd

Calving reconnaissance surveys on the Ahiak calving ground were carried out in 2006, 2007, 2008 and 2009, over the same period of the recent Bathurst decline (A. Kelly, ENR unpublished data). The methods for these surveys were the same each year and involved visual counts within a defined transect flown at 400 feet above ground. These surveys do not provide a precise population estimate, but when done consistently, they give a clear index of trend.

Preliminary analysis of the average number of caribou seen per 10-km survey segment on the Ahiak surveys suggests that the number of cows on the Ahiak calving ground in 2009 was about 40% of the number in 2006 (Figures 4.4 & 4.5). A substantial decline in Ahiak caribou from 2006 to 2009 makes it rather unlikely that there was a large movement of Bathurst caribou to the Ahiak range over this period.

Figure 4.4. Average number of breeding cows, non-breeding cows, and adult cows (sum of breeding and non-breeding cows) observed per 10-km flight line segment on transect during calving reconnaissance surveys in June 2006, 2007, 2008 and 2009 on the Ahiak calving ground.

The cause of the apparent Ahiak decline is not clear. An initial study of body condition in Ahiak cows in February 2009 (A. Kelly, ENR unpublished data) suggested that the caribou in this herd were leaner than Bathurst caribou assessed in March 2008, but pregnancy rates were normal. Of 28 caribou satellite collared in April 2008 on Ahiak/Beverly range, less than half were pregnant, which may suggest nutritional limitation that year (D. Johnson, ENR, unpublished data). If the low pregnancy rate was representative of the overall herd, then the low number of cows per transect segment in 2008 may in part reflect a higher than normal proportion

of non-pregnant caribou cows not reaching the calving grounds that year. Non-pregnant cows are more likely to be on the periphery of a calving ground, or off the calving ground entirely, than breeding cows. We found that a number of Ahik collared cows did not reach the calving grounds in June 2008, and several were on the periphery. We suspect that the total number of cows in Figure 4.4 for 2008 is an under-estimate, and that the increase from 2008 to 2009 is spurious. The actual population trend from 2007 to 2009 was more likely a continuous decline.

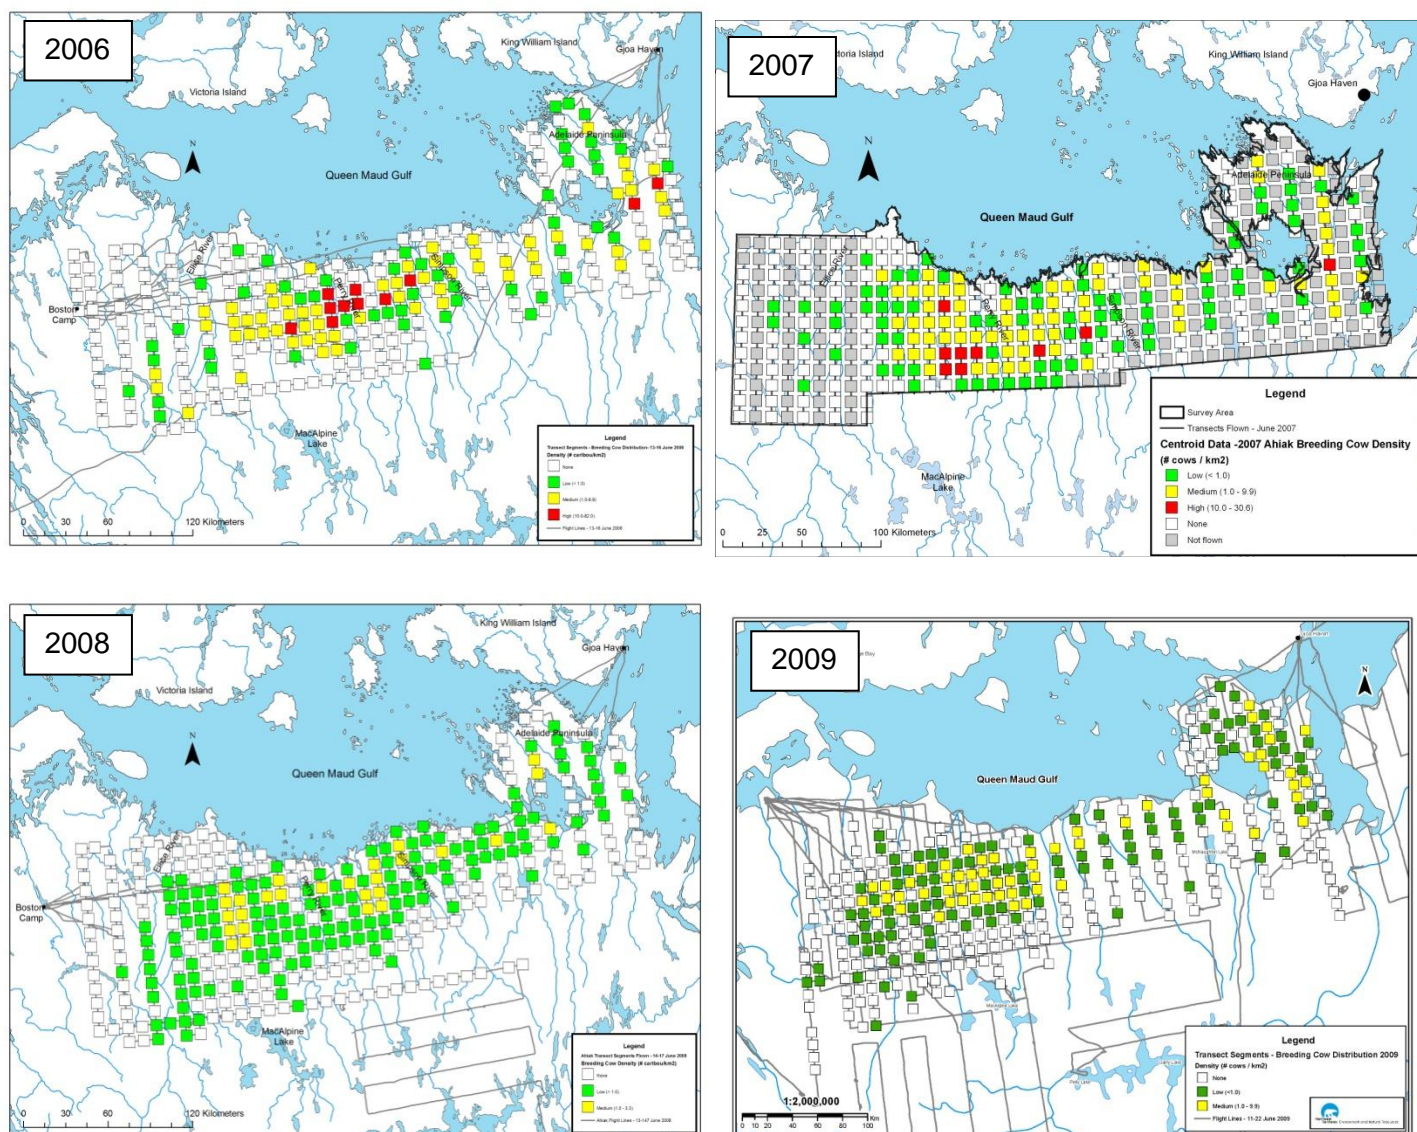

Figure 4.5. Map showing flight lines over the calving ground of the Ahik herd in 2006, 2007, 2008, and 2009 (D. Johnson, A. Kelly, ENR, unpublished data). The squares are 10-km segments along flight lines. Red squares had at least 10 breeding cows per square km (high density), yellow squares had 1-9.9 breeding cows per square km (medium density), green squares had less than 1 breeding cows per square km (low density), and white squares had no breeding cows. There were no red high-density segments in 2008 or 2009.

4.3 Population trend in the Bluenose-East Herd

In 2000 this herd was estimated at $119,600 \pm 25,400$. From 2000 to 2006, its numbers dropped by nearly 50% to $70,100 \pm 8,100$ in 2005 and $66,800 \pm 5,200$ in 2006 (population estimates from Nagy and Tracz 2006,

Nagy et al. 2008, Nagy 2009a). A post-calving photo survey of this herd was attempted in July 2009, but was unsuccessful because caribou did not group up into tight groups suitable for photography.

Figure 4.6. Population estimates for the Bluenose-East herd, 1985-2008.

Although the 2009 survey was not successful, over 100 hours were flown on the survey by biologist Boyan Tracz and associates, who carried out the previous surveys of this herd in 2005 and 2006. His observations suggested a decline from 2006 but he was unable to estimate the size of the decline. There was no evidence of a large influx of caribou.

4.4 Extent of Aerial Survey Coverage on GNWT caribou surveys in 2007, 2008 and 2009

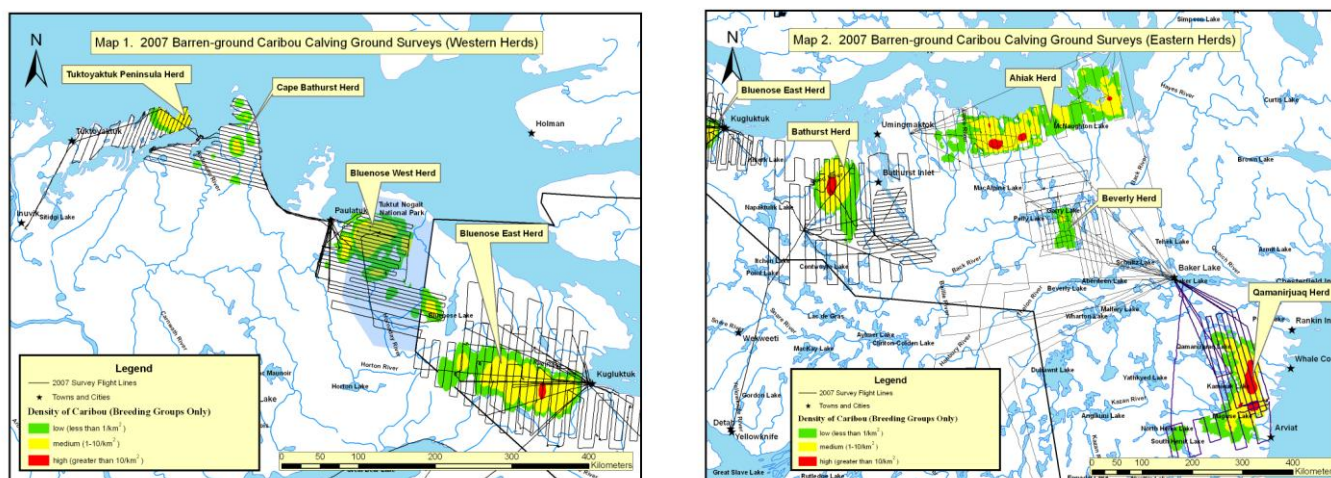

Figure 4.7a. Survey lines flown by GNWT staff in June 2007 over calving grounds of the Tuktoyaktuk Peninsula, Cape Bathurst, Bluenose-West, Bluenose-East, Bathurst, Beverly, Ahlak and Qamanirjuaq herds.

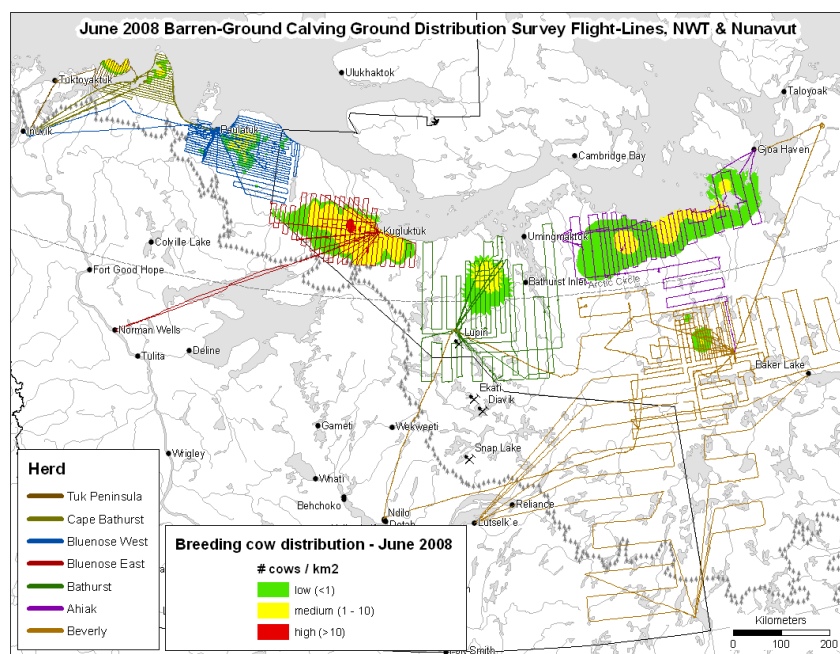

Figure 4.7b. Survey lines flown by GNWT staff in June 2008 over calving grounds of the Tuktoyaktuk Peninsula, Cape Bathurst, Bluenose-West, Bluenose-East, Bathurst, Beverly and Ahiak herds.

In June 2007 and June 2008, GNWT biologists flew the flight lines shown in Figure 4.7a&b near the peak of calving for each calving ground for the herds shown. Flight lines were extended until no further groups of calving cows had been seen for at least 10 km. Additional lines were flown between calving grounds, and in the case of the Beverly calving ground, a second plane was used to fly areas north, south, east and west of the traditional calving ground to be certain that no significant groups of breeding cows were missed.

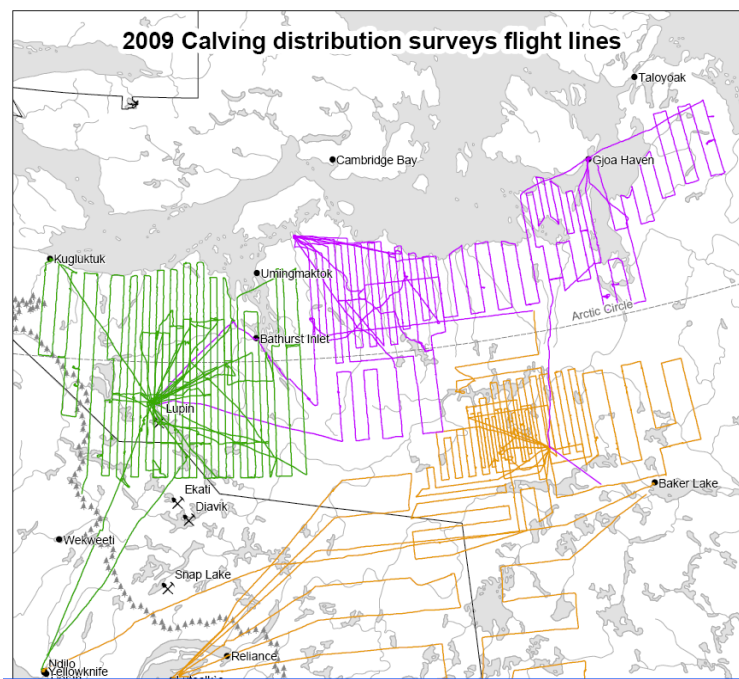

Figure 4.8. Aerial flight lines flown over the Bathurst, Ahiak, and Beverly calving grounds in June 2009.

In June 2009 (Figure 4.8), 59,000 km of flight lines were flown over the Bathurst, Ahiak, and Beverly calving grounds. Flight lines covered the area between the Ahiak and Bathurst calving grounds, and were continued west from the Bathurst calving ground to the beginning of the Bluenose-East calving ground. Areas around the Beverly calving grounds were flown by a second survey aircraft. With this level of survey flying, and satellite collars confirming cows in each herd on their expected calving ground, the likelihood of missing large groups of calving caribou cows is low.

4.5 Fidelity to calving grounds: evidence from other herds

Fidelity to a calving ground is defined as the annual return of breeding cows to the geographic area used for calving in previous (recent) years. Fidelity to calving grounds is the basis of barren-ground caribou herd definition, which has a 40 year history across the North American range (Gunn and Miller 1986, Gunn et al. 2008a). Fidelity to calving grounds is also the key assumption underlying the use of the June censuses to track the trend in breeding females. Annual evidence for fidelity of cows to the Bathurst calving grounds has been addressed in census survey reports (Gunn et al. 2005b, Nishi et al. 2007).

Overall, the rates of collared cows switching between calving grounds for the Bathurst, Ahiak and Bluenose-East herds are similar to the rates recorded elsewhere between neighbouring herds. The low rate of switching between the Bathurst and neighbouring herds is similar to, for example, the Teshekpuk herd: Person et al. (2007) documented an annual apparent emigration rate of 0.07 ± 0.03 (five cows from 73 caribou years, 1990-2005). Only one of 175 cows satellite collared between 1981-1990 switched calving grounds between the neighbouring Mentasta and Nelchina herds (Lieb et al., 1994). Rates of switching were higher between the George River and Leaf River herds in northern Quebec and Labrador. Boulet et al. (2007) recorded that 14 of 149 satellite-collared cows switched calving grounds (1986-2003). Most of the switches were George River cows moving to the Leaf River range for at least one calving season (whether they calved was not recorded). The annual rates of switching calving grounds were 6.6% and 0.9% of the George River and Leaf River collared cows, respectively. Six of 13 cows (one cow had only two calving locations) reversed and returned to their earlier calving ground. Two cows spent an equal number of years on either calving ground (six and eight years). Valkenburg et al. (2003: 43) stated for Alaskan herds: "The last 20 years of data from satellite collaring and radio-tracking caribou indicate that caribou herds can be considered closed populations for the purposes of population management."

Spatial fidelity (directed migration) is likely the mechanism whereby caribou maintain their associative (gregarious) calving. Combined with synchronous calving, gregarious calving helps reduce predation risk (Bergerud et al. 2008) and allows nursing cows to take advantage of early appearance of green forage (Griffith et al. 2002, Post et al. 2003).

Reduction in geographic fidelity to a calving ground, or cows not returning to traditional calving grounds, has rarely been recorded. The conditions under which geographic fidelity is reduced include delay in pre-calving migration due to snow conditions. Under those conditions the calving ground is elongated along the main direction of pre-calving migration and this has been recorded for both the Beverly (1979) and the Qamanirjuaq herds (2005) (Gunn et al. 2007, 2008a) as well as the Porcupine herd in 2001 (Griffith et al. 2002). Calf survival under these circumstances is usually low but much higher when caribou calve on their preferred calving grounds (Griffith et al. 2002).

On the Alaskan coast, three of five collared cows from the Teshekpuk herd calved on the neighboring Central Arctic herds range in 2004 but the preceding fall, severe icing conditions may have induced a third of the herd (including five collared cows) to migrate east. Then during spring migration in May 2004, Carroll (2005) reported that a combination of the Trans Alaska Pipeline, the Dalton Highway and the flooding Savaganirktok River delayed the Teshekpuk migration. Two collared cows eventually continued migration west but calved before they reached the usual calving ground of the Teshekpuk herd. The other three collared cows calved on the Central Arctic herd's calving ground. In 2000 and 2001, spring break-up was late on the pre-calving ranges

of the Western Arctic Herd in Alaska and 28% and 91%, respectively, of the breeding cows were south of the traditional calving grounds during the peak of calving (Dau 2003).

The persistence of geographic fidelity to traditional calving grounds varies between herds with some herds such as the Beverly and Qamanirjuaq showing a high degree of annually repeated use over decades (Gunn et al. 2007). The Bathurst herd shows two clusters of years with high geographic fidelity punctuated by a few years of lower geographic fidelity as the geographic location shifted from east to west of Bathurst Inlet (Gunn et al. 2008b).

Fidelity to calving areas is a relatively general phenomenon in many migratory large-bodied herbivores (Bolger et al. 2007) and in pelagic marine mammals. In caribou, the breeding cow's geographic fidelity is the consequence of the directional pre-calving migration (Bergerud et al. 2008). The strength of this can be seen in the satellite collar cows that abruptly change direction from heading to one calving ground to 'their' calving ground during pre-calving migration for the Bathurst herd (Gunn et al. In prep.), and for the George River herd (Bergerud et al. 2008).

Delayed pre-calving migration reduces geographic fidelity. Another cause of reduced geographic fidelity to calving grounds is also rare and is 'swamping' of one calving ground by cows from a neighboring calving ground. The two published examples are from mountain caribou in Alaska. Between 1979 and 1987, the calving grounds of the smaller Yanert herd (500-1000 caribou) and the larger Delta herd (4000-8000 caribou) were only 10 – 50 km apart after the Delta herd's calving ground had shifted (Davis et al. 1986). In the second example, the smaller Kilbuck herd's (ca. 4000) traditional calving ground was within 25 km of the larger Mulchatna's (ca. 200,000) shifted calving ground in 1994 (Valkenburg *et al.*, 2003, Hinkes et al. 2005) and the herds combined. The smaller mountain herds (Yanert and Kilbuck) had different calving strategies (scattered rather than gregarious) than the larger herds. The larger herds with gregarious calving expanded their winter and summer ranges and each overlapped a small neighboring herd.

Analyses of the Ahiak and Beverly satellite-collared cows since 2006 suggest a possible reduction in the fidelity of some cows to the traditional Beverly calving ground. Two related effects may be involved. The Ahiak herd's elongated east-west calving ground is directly north of the Beverly calving ground (see Figure 3.4) and thousands of Ahiak cows heading north may have passed near the Beverly calving ground or directly through it. It is possible that cows from both herds migrating to their calving grounds continued together on to the Ahiak calving ground. Given the generally high fidelity of cows to calving grounds, this is only likely to have happened if the Beverly herd had first reached very low numbers. It is possible that to maintain effective densities (gregariousness or predator swamping), some Beverly cows migrated to the higher densities on the Ahiak calving grounds. If the densities on the Beverly calving grounds were below a density threshold for gregarious behavior, this would be an example of an Allee Effect, which is a decline in survival or reproduction with declining density (Stephens and Sutherland 1999).

It is worth remembering that the primary reason barren-ground caribou herds are able to reach numbers in the tens and hundreds of thousands is that temporally concentrated calving in areas with limited predator numbers allows them to "escape" the limitation that predators (principally wolves) exert over woodland caribou, which never reach nearly the population size of barren-ground herds (Seip 1991, Bergerud et al. 2008). The high mortality, poor calf survival and apparent shift to a calving ground with much higher numbers of cows by Beverly caribou may reflect the fact that at very low numbers, scattered numbers of cows and calves may be vulnerable to a limited number of predators. In effect, the relations between Beverly caribou and predators may now be similar to those normally experienced by woodland caribou, which are often held at low densities by predators (Seip 1991, Bergerud 2000).

The Fortymile herd's history can also serve as a cautionary tale. This Alaska/Yukon herd was estimated at 350,000-568,000 in the 1920's, when the herd took several days to cross the Yukon River. This herd declined to 46,000-60,000 by 1950, in part due to heavy harvests, then declined further to an estimated 5,000 in the

1970's (Davis et al. 1978, Alaska Board of Game 2006). By this point it occupied just a fraction of its former range. Between 1974 and 1990 the herd grew to about 23,000, then remained at that level until 1995, in large part due to low calf survival (Alaska Board of Game 2006). As a result of a focused predator control program, the Fortymile Herd increased to 43,000 by 2003. This may be another example of a herd that declined to such low numbers that the fundamental relationship with predators changed to one characteristic more of woodland caribou than of large migratory herds of barren-ground caribou.

5.0 Bathurst herd decline: field data

In this section, we review the results of population surveys, other surveys and related studies carried out for the Bathurst herd.

5.1 Field data from the June 2009 calving ground survey (JN & BC)

Aerial photographic surveys of annual calving grounds have been the primary means of estimating abundance of breeding females for the Bathurst herd of barren-ground caribou since the early 1980s (Heard 1985). To maintain comparability with previous surveys, we used the calving ground photo-census technique and estimated the number of breeding females on the annual calving ground in June 2009; we briefly report results here and note that an extensive survey report is currently in preparation.

5.1.1 Methods

Multiple aircraft and a relatively large field crew were coordinated to conduct and complete the June 2009 calving ground survey in a timely fashion (Appendix 1). The survey was initiated on the 3 June with mobilization of a field crew to the base of operations, which was the Tahera mine site at the northern end of Contwoyto Lake. We commenced the systematic reconnaissance survey on the 4 June using a Cessna Grand Caravan. A second fixed-wing aircraft (Turbo Beaver) and field crew arrived on the 6 June to assist with the systematic survey. By the 7 June, we had delineated the annual calving ground and determined boundaries and sampling effort for photographic and visual survey strata (Figure 5.1). Additional systematic surveys were conducted from the 8-10 June to expand survey coverage over a broader area of the extent of calving and to confirm that we had delineated the entire annual calving ground and not missed breeding females in adjacent areas (Figure 5.1). On the 17 June, additional flight lines were added to the systematic survey coverage in the area to the west and north of Napaktulik Lake towards Kugluktuk (Figure 5.1).

Based on observed densities, composition of caribou (i.e., antlered cows with newborn calves), and relative abundance of newborn calves seen during the systematic survey, the annual concentrated calving ground was delineated into a high and medium stratum for aerial photography, plus three low density strata for visual estimation of caribou from fixed-wing aircraft (Figure 5.2). The photographic and visual surveys were initiated on the 8 June and completed on the 9 June.

Aerial photography was conducted using similar methodology, aircraft, and camera equipment as previous surveys in 1996, 2003, and 2006 by Geographic Air Survey Ltd. Caribou on aerial photographs from the high and medium density strata were enumerated by H.P. Roy (Ottawa, ON.) using similar methodology from previous surveys (see Nishi et al. 2007), and counts of caribou were summed across all photographs along a transect. Composition surveys were initiated on the 8 June to estimate the proportion of breeding females in each of the survey strata and completed on the 11 June.

5.1.2 Results

The estimated abundance of 1+ year-old caribou on the annual calving ground of the Bathurst herd in June 2009 was 23,273 (\pm 2,788 SE) (Table 5.1, Appendices 1B, 1C, and 1D). Approximately 98% of the estimated

caribou on the calving ground occurred within the high (75.6%) and medium (22.6%) photographic strata, whereas the three visual strata comprised less than 2% of the estimate (Table 5.1).

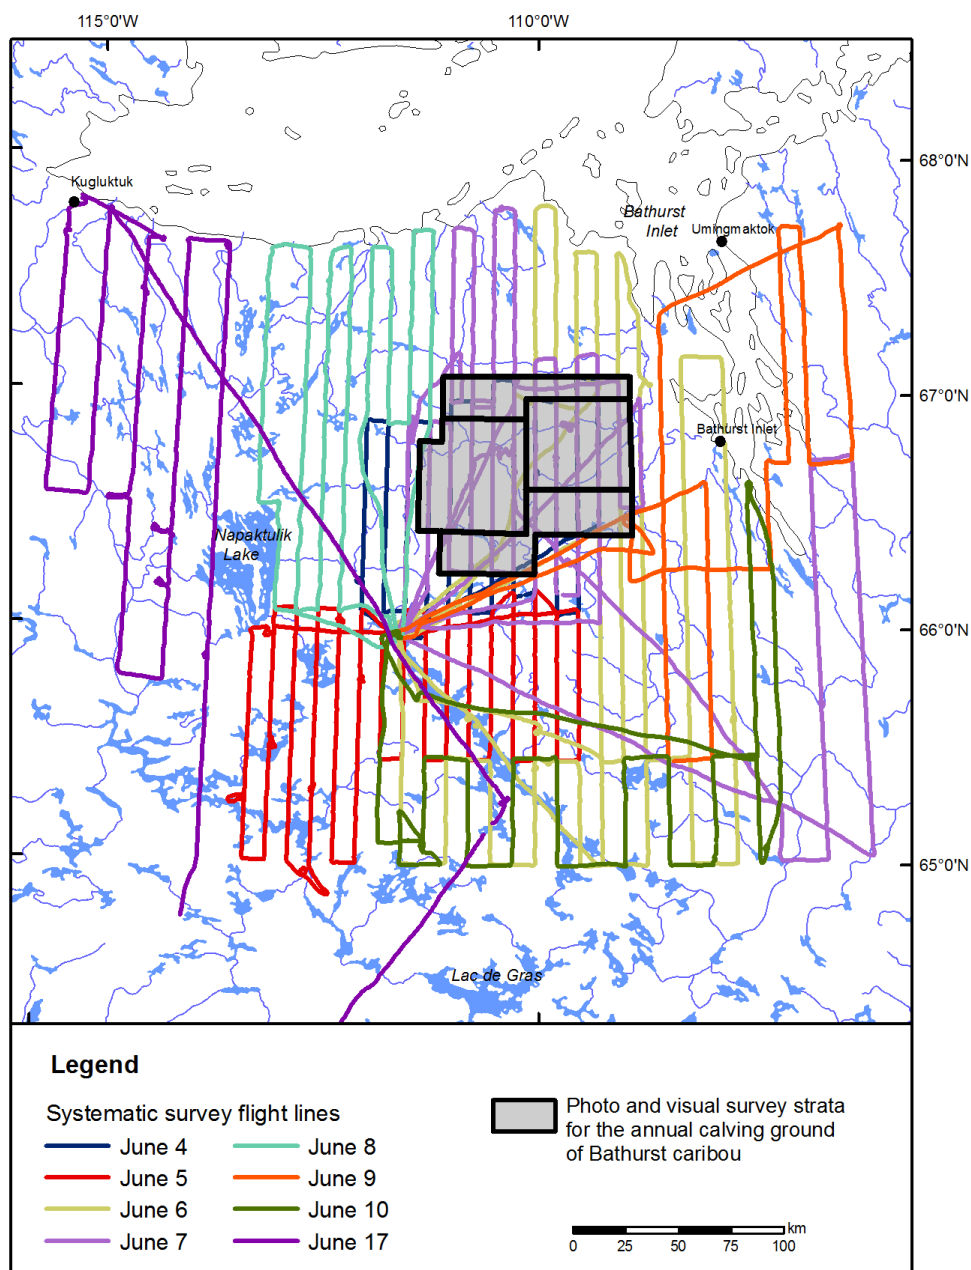

Figure 5.1. A systematic reconnaissance survey to delineate the annual calving ground of the Bathurst herd of barren-ground caribou, June 2009.

During the composition survey, a total of 2,939 1+ year-old caribou were observed within 91 groups across the survey strata (Table 2, Appendices E, F, and G). The proportions of breeding females in the high and medium strata were $0.678 (\pm 0.043 \text{ SE})$ and $0.879 (\pm 0.017 \text{ SE})$ respectively (Table 5.2). Given the low densities of caribou in the three visual strata, only 9 groups comprising a total of 226 1+ year-old caribou were classified in the low strata, resulting in a proportion of breeding females of $0.113 (\pm 0.048 \text{ SE})$.

After adjusting for the observed proportion of breeding females in the survey strata, the abundance of breeding females on the 2009 annual calving ground was estimated to be 16,604 ($\pm 2,176$ SE) animals (Table 5.3).

Extrapolation of the abundance of breeding females on the annual calving ground to an estimate of total herd size is dependent on assumptions regarding a) sex ratio, and b) the pregnancy rate for breeding females.. When the proportion of females in the population was set at 0.730 to reflect fall composition data from 2008, the extrapolated population estimate was 31,897 ($\pm 6,092$). We include in Table 5.4 the extrapolated population estimate using the earlier sex ratio (38,245) but the lower population estimate is the appropriate one to use. It should be noted that in the extrapolated 2006 population estimate used previously, the proportion of females was set at 0.60, the average of several fall sex ratio results. However, since that time results of fall surveys in 2004, 2006, 2007 and 2008 indicate that the Bathurst herd has had sex ratios lower than expected. Using the 2004 sex ratio, the more correct 2006 extrapolated population estimate is 106,000.

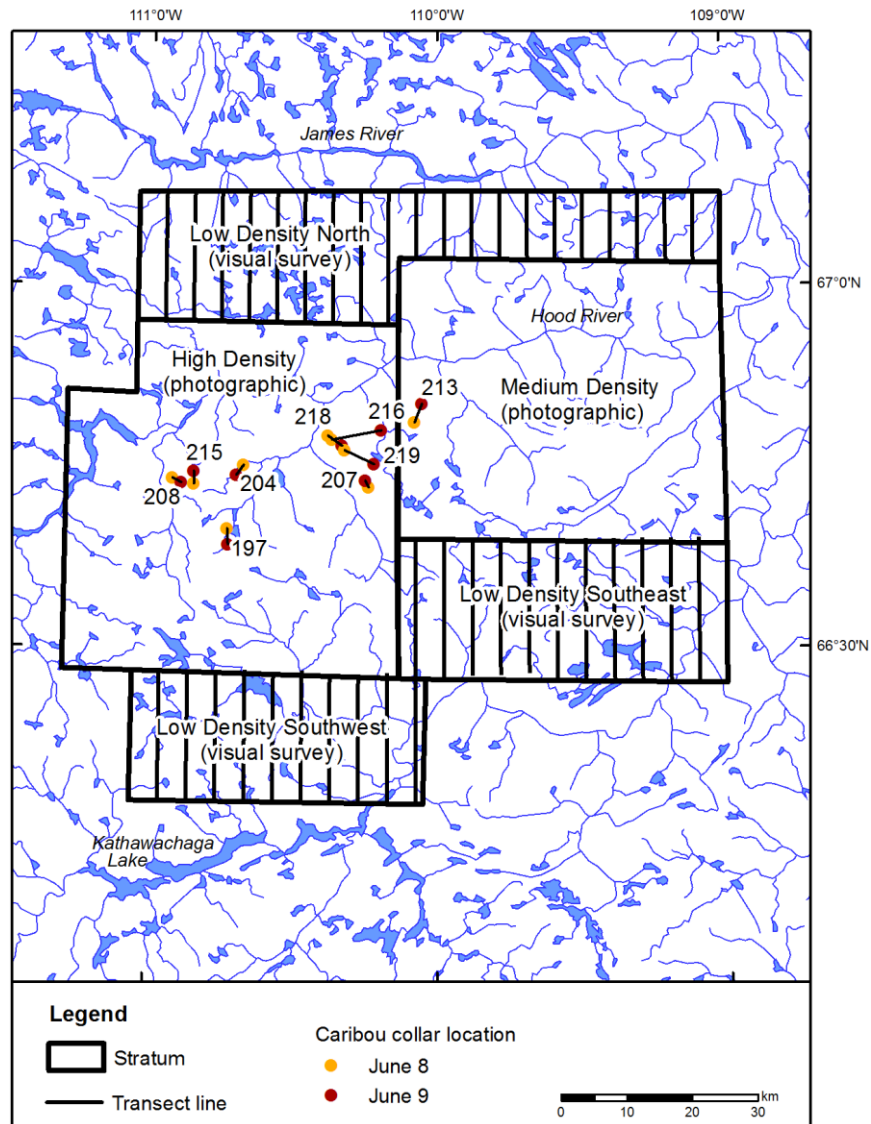

Figure 5.2. Photographic and visual survey strata delineated on the annual calving ground of the Bathurst herd of barren-ground caribou, June 2009. Locations of nine satellite collared cows are also shown within photographic strata on the 8 and 9 June.

Table 5.1. Analysis of data from an aerial survey of the Bathurst caribou calving ground, 8-9 June 2009.

Low density - visual (South)	9	25	226	0.113	0.048	0.423
Sum	91	2,033	2,939			

5.1.3 Discussion

The estimate of breeding females ($16,605 \pm 2176$ SE) from the June 2009 calving ground photo-census of the Bathurst herd was relatively precise with a Coefficient of Variation (CV) of 0.129, and shows a significant decline ($t = 4.27$, $df = 21$, $P < 0.005$) relative to the June 2006 estimate of $55,593 (\pm 8813$ SE) (Nishi *et al.* 2007). The following section provides a more detailed assessment of the trend of the Bathurst caribou herd. The design and execution of the June 2009 calving ground survey was efficient, and we did not incur any major problems that could have seriously affected credibility of survey results. There were no delays in the timing between the systematic reconnaissance survey, stratification and completion of the photo-census and composition surveys of high and medium density strata. As the photo-census was completed within 2 days following stratification, there was minimal potential for movements of breeding females across survey strata to bias the calving ground estimate. Movement rates of satellite collared Bathurst caribou cows suggested that the peak of calving occurred on the 6-9 June 2009. Occurrence of those nine collared cows within the high and medium strata (Figure 5.2) also supports our assertion that we had effectively delineated the annual calving ground and did not miss a substantial portion of breeding females outside the surveyed area.

Table 5.3. Estimated number of breeding females in high, medium and low density strata of the Bathurst calving ground, June 2009, based on stratum population estimates and composition counts.

Stratum	Estimated number of 1+- year-old caribou on calving ground	Proportion of breeding females	Estimated number of breeding females	Variance	Standard Error	CV
High	17,593	0.678	11,928	3,236,450	1,799	0.151
Medium	5,267	0.879	4,630	1,499,906	1,255	0.265
Low N	28	0.113	3	10	3	0.988

Total population estimate	31,897	5345.1	0.17	20965	42829

5.2 Trend in Bathurst caribou breeding females from multiple calving ground photo-surveys (JB)

In this section, we review changes in the numbers of breeding females in the Bathurst herd over time, with an emphasis on population trend, particularly between 2006 and 2009.

5.2.1 Data set used for analysis

The data set of population estimates for breeding females is shown in Figure 5.3. The data on abundance of breeding females are the most applicable data set for trend estimation since breeding females are the most biologically meaningful segment of the population. In addition, all parameters (i.e. counts of caribou and composition) are directly estimated for each year surveyed and therefore breeding female counts should most directly reflect changes in population size. The survey methods were the same for all surveys.

Figure 5.3: Population estimates of Bathurst breeding females for surveys conducted in 1986, 1990, 1996, 2003, 2006, and 2009. Ninety-five percent confidence intervals for estimates are shown as error bars.

5.2.2 Weighted regression

Weighted least squares analysis was used to estimate trend from the time series of data (Brown and Rothery 1993). Each population estimate was weighted by the inverse of its variance to account for unequal variances of surveys, and to give more weight in the estimation to the more precise surveys.

Unlike previous surveys, there was evidence of potential non-linear population trends as indicated by the substantially lower 2009 calving ground estimate. Given this, we conducted substantial testing for non-linear population trends using the sample-size-corrected Akaike Information Criterion (AICc) index of model fit (Burnham and Anderson 1998). The model with the lowest AICc score was considered the most parsimonious, thus optimizing the tradeoff between bias and precision (Burnham and Anderson 1998). The difference between any given model and the most supported (ΔAICc) was used to evaluate the relative fit of models when their AICc scores were similar. In general, any model with a ΔAICc score of ≤ 2 is considered to be supported by the data. Analyses were conducted with proc GENMOD and proc REG within SAS statistical package (SAS Institute 2000).

The population size was log transformed to partially account for the exponential nature of population change (Thompson 1998). Unlike previous analysis, it was not possible to estimate rates of change from λ given potential non-linear trends in the data set. However, λ could still be estimated using the ratio of successive predicted population sizes from the regression model. The per capita growth rate can be related to the population rate of change (λ) using the equation $\lambda = e^r = N_{t+1}/N_t$. If $\lambda = 1$ then a population is stable. If λ is less than 1 then the population is decreasing, and if λ is greater than 1 then the population is increasing.

5.2.3 Monte Carlo simulation

We used a Monte Carlo simulation technique to allow another estimate of the variance in trend that resulted from individual variances of each of the surveys (Manly 1997) and provide confidence interval for λ . The basic

question this simulation asked was: “If these studies were repeated many times, would the estimated trends and associated variances be observed given the levels of precision of each of the surveys?” The following procedure was used for simulations:

1. *The sampling procedure for each year was simulated using estimates of variance from each survey.* The estimated mean and variance were used from each survey to generate random population sizes for each of the years of the survey. This is best explained in terms of confidence interval estimation. For a given estimate the 95% confidence interval is the population estimate $\pm t_{(\alpha=0.05, 2, df)} \text{ * standard error}$. For each simulation a random t-distribution variate with associated degrees of freedom for each survey was generated. This random variate was then multiplied by the standard error and then added to the population estimate resulting in a random population size that followed the general probabilistic distribution of estimates. If done repeatedly, this procedure would create a distribution of estimates for each of the surveys that fell within the given confidence intervals. Formulas of Gasaway et al. (1986) were used to estimate degrees of freedom for t-statistics.
2. *The sampling procedure was simulated and trend estimates were estimated using regression analysis.* A random set of population sizes was generated for each of the 5 sampling occasions using the procedure documented in point 1 and the parameters listed in Table 1. The most supported AIC regression model was used for estimation. This procedure was repeated for 2000 pseudo data sets that resulted in 2000 estimates of trend. The most supported trend model was used to produce trend estimates.
3. *Estimates of trend from the pseudo data sets were analyzed.* Mean estimates and percentile-based confidence intervals based on successive changes in population size were estimated using the pseudo data sets.

Basically, this analysis determined the maximal and most likely range of trend estimates that could be observed from this data set when the variance of each of the surveys was accounted for.

5.2.4 Results: Weighted regression

Model selection results suggested that a nonlinear trend best approximated by a cubic polynomial term was most supported (Tables 5.5 & 5.6). This model showed strong support as indicated by an AIC weight of 0.95. A model with linear trends was not supported by the data.

A plot of the regression line (back transformed to population size units) is shown in Figure 5.4. The gray lines are 95% confidence interval around the trend line. The circles are data points. The confidence intervals are irregular since they are accounting for varying degrees of variance in each of the point estimates. For example, the 1986, 2003, and 2006 and 2009 surveys had the best precision and therefore the confidence intervals are tightest around these points.

Table 5.5: Model selection results for Bathurst trend analysis. Akaike Information Criteria (AIC_c), the difference in AIC_c values between the i th and most supported model (ΔAIC_c), Akaike weights (w_i), and number of parameters (K) are presented.

model	AIC_c	ΔAIC_c	w_i	logl
yr^3	2.82	0	0.995	2.59
$yr+yr_{>06}$	8.12	5.30	0.005	4.94
$yr^2 yr^3$	11.58	8.76	0.000	3.21
$yr yr^3$	12.50	9.68	0.000	2.75
$yr yr^2$	17.68	14.86	0.000	0.16
$yr+yr_{>03}$	20.59	17.77	0.000	-7.29
yr	34.91	32.09	0.000	-13.46
$yr yr^2 yr^3$	37.04	34.22	0.000	5.48
intercept	322.72	319.90	0.000	-159.86

Parameter estimates for the most supported model suggest both the intercept and yr^3 terms are significant (Table 5.5).

Table 5.6: Regression model parameter estimates for Bathurst trend analysis.

Parameter	Estimate	S.E	C.I. low	C.I. high	t	P-value
Intercept	12.208	0.075	12	12.417	162.72	0
yr^3	-0.0002	0.000015	-0.0002	-0.0001	-13.45	0.0002

Figure 5.4: Predicted trend for breeding females from weighted least squares regression analysis. Grey lines are confidence interval on predictions. Circles are estimates of breeding females for a given year.

5.2.5 Results: Monte Carlo simulation

Monte Carlo simulation results suggested that the trend was increasingly negative as shown by lower λ estimates for each year. The λ of 1 at the beginning of the simulations was an artifact of the fact that this was

the first point in the simulation and therefore the most applicable estimates were for the latter part of the time series, i.e., after 2000 (Figure 5.5).

Figure 5.5a: Simulated estimates of λ as a function of year from Monte Carlo simulation analysis.

A histogram of λ estimates for 2009 shows that none of the values overlapped 1, suggesting there was no statistical chance that the population was stable.

Figure 5.5b: Distributions of population rate of change (λ) for 2009 generated using Monte Carlo simulation trials.

The estimates of λ from the Monte Carlo analysis for 2009 is 0.76 (SE=0.17, CI=0.74 to 0.80) with a corresponding r estimate of -0.26 (SE=0.027, CI=-0.31 to -0.22).

5.2.6 Discussion: trend in breeding females in the Bathurst caribou herd

Both analyses reported here suggest an increasing negative trend in the population size of breeding females in the Bathurst caribou herd. From inspection of Figure 5.3 it might be surmised that the population declined between 1986 and 1990, then stabilized from 1990 to 1996, then declined from 1996 to 2006, then declined further from 2006 to 2009. The cubic polynomial trend model is the “best approximating model” in that it best summarizes the trends in population size using the least number of parameters, as displayed in Table 5.5.

Regression methods that utilize multiple years of data provide potentially more inference regarding population trend and status compared to 2 sample t-tests of sequential population estimates. For example, regression-based estimates of r and λ express population change in yearly units. In comparison, t-tests of sequential estimates will be influenced by the arbitrary period of time between successive surveys. For example, a 2 sample t-test will be more likely to detect a change in population size between surveys that are conducted at longer time intervals even if the population is changing at a constant rate. Estimates from regression are not influenced by survey interval, and they utilize data from all surveys conducted, leading to higher overall power to detect change in population size. For this reason we recommend reporting trend estimates in terms of λ and r -values rather than the results of t-tests of sequential estimates.

5.3 Bathurst calving ground distribution surveys (JN & BC)

The Bathurst calving ground photo-census starts with a systematic aerial reconnaissance survey to determine the relative composition and density of caribou and delineate the extent of an annual calving ground. Systematic aerial reconnaissance surveys are comparatively less expensive and can provide a useful comparative dataset to track trend in caribou densities on a calving ground. They can be conducted during intervening years between full-scale calving ground photo-censuses. We briefly describe a comparison of caribou densities on the Bathurst calving grounds from systematic reconnaissance surveys and show that those data also indicate a dramatic decline in caribou density since 2003. Thus, systematic reconnaissance surveys provide an additional and useful index for trend of breeding females.

5.3.1 Methods

Estimates of 1+ year-old caribou were available from completed calving ground photo censuses in 2003 (Gunn *et al.* 2005b), 2006 (Nishi *et al.* 2007), and 2009 (this report). Systematic aerial reconnaissance surveys of the Bathurst calving grounds were conducted in 2003, 2006, 2007, 2008, and 2009 (GNWT unpublished data). Data from systematic surveys were reported as caribou densities within adjacent transect segments (0 km long segments by 0.8 km wide) oriented along north-south oriented linear transects, within a systematic grid of transects spaced at 10 km intervals.

We delineated the boundaries of the annual calving ground based on composition and density of caribou observed during each systematic survey. We multiplied density estimates for each transect segment by 100 to extrapolate the observed density within a transect segment to a count of caribou within adjacent 10 km x 10 km cells of the delineated calving ground. The sum of caribou counts within all 100 km² cells provided a coarse extrapolated estimate of 1+ year-old caribou on the annual calving ground based on the systematic reconnaissance surveys.

5.3.2 Results

The extrapolated estimates of 1+ year-old caribou on the Bathurst calving grounds were consistently lower, but showed a similar declining trend to that depicted by the caribou estimates derived from aerial photo-censuses (Figure 5.6). Extrapolated estimates based on observed caribou densities from systematic reconnaissance surveys showed the decline from 2006 to 2009 on an annual time step.

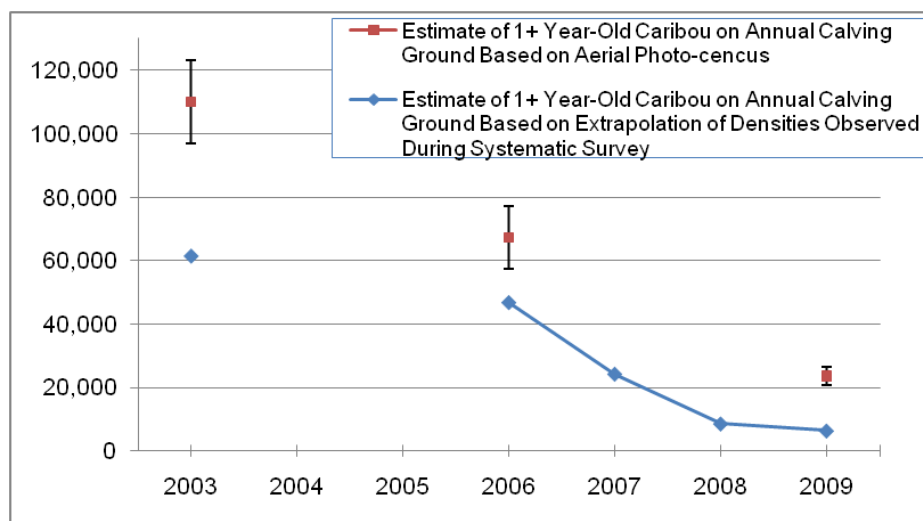

Figure 5.6. Trend in estimates of 1+ year-old caribou on Bathurst calving grounds based on aerial photo-census results and extrapolation of caribou densities observed during systematic reconnaissance surveys.

5.3.3 Discussion

Recent systematic reconnaissance surveys of the annual Bathurst caribou calving grounds are consistent with results from calving ground photo-censuses and show a continued and dramatic decline in numbers of caribou on the calving grounds.

Systematic reconnaissance surveys provide a useful and comparatively economic way of monitoring trend of caribou on an annual calving ground, and allow managers to anticipate trend during the intervening years between full-scale calving ground photo-censuses. In addition to monitoring abundance of 1+ year-old caribou, results from systematic reconnaissance survey of caribou calving grounds can provide insight on trend in spatial extent of the annual concentrated calving area and associated spatial patterns and changes in caribou densities. However, observer bias associated with sightability and counting error will be a source of uncertainty and variability that will affect precision and accuracy of this visual survey technique. Therefore, careful and consistent standardization of survey methods and rigorous training of observers will help to improve the value of systematic reconnaissance surveys. Systematic reconnaissance surveys may be a particularly important annual monitoring tool when caribou populations (such as the Bathurst herd) decline to low numbers and management actions are implemented to assist in recovery.

5.4 Composition surveys in the Bathurst herd and other herds (DC & BC)

Biologists working with the Bathurst herd recorded spring or late-winter calf:cow ratios in the mid-late 1980s, early 1990s, and from 2001 to present (2009). In brief, each survey is preceded by a systematic fixed-wing reconnaissance survey to verify where the main aggregations of caribou are. The locations of satellite collared females are helpful in guiding the reconnaissance survey. Areas of known overlap in satellite collars with neighbouring herds are avoided. Total numbers of caribou classified in the 2006-2009 surveys ranged from 4,346 to 10,121, and numbers of groups classified ranged between 97 and 286.

The calf:cow ratios recorded from 1985 to 2009 fall into 3 distinct periods: 1985-1995, with ratios between 30 calves:100 cows and 50 calves:100 cows; 2001-2006, with ratios at most of 30:100 and as low as 8.5:100 in 2006; and 2007-2009, with values between 37 calves: 100 cows and 50 calves:100 cows.

Figure 5.7. Spring (March-April) calf:cow ratios for the Bathurst herd, 1985-2009. As a rough rule of thumb, calf:cow ratios of about 30 calves: 100 cows (orange bar) are associated with stable caribou herds, but higher recruitment may be needed for stability if cow mortality rates are higher than normal.

For a wide range of caribou herds, Bergerud (2000) identified values around 30 calves: 100 cows as indicative of stable herds, as a rough rule of thumb. However, modeling of the Bathurst herd (see section 7.2) suggests that calf survival of 32-35% would be sufficient for stability at a cow survival rate of 91%, but at a lower cow survival rate of 86%, calf survival of 50-53% would be needed for stability.

Population surveys in 1986, 1990 and 1996 indicate that the herd was stable or declining slowly over this period. Calf:cow ratios of 30-50:100 might have been sufficient for a stable herd or one increasing slightly. However, if cow survival rates were around 86% or lower, these calf:cow ratios might not have been sufficient to maintain a stable herd.

The calf:cow ratios from 2001 to 2006 are less ambiguous: the herd would almost certainly have been declining over this period for natural reasons, regardless of harvest, with several weak cohorts, particularly in 2005 and 2006. Adult survival and calf survival tend to be correlated (Bergerud 2000), hence natural cow survival in the Bathurst herd might also have been low in these years.

The calf:cow ratios in 2007, 2008 and 2009 are similar to the values recorded for this herd in the 1980s and 1990s, and may be an indication of improving environmental conditions. These ratios may be somewhat inflated due to high cow mortality rates from hunting: if cows were shot and calves left alive, the calf:cow ratio might suggest better calf survival than actually occurred. However, calf:cow ratios in 4 other NWT herds (Ahiak, Bluenose-East, Bluenose-West, and Cape Bathurst) were all between 40 and 50 calves:100 cows in March/April 2008, possibly indicating a larger-scale improvement in environmental conditions (ENR unpublished data).

Spring calf:cow ratios recorded for the neighboring Bluenose-East and Ahiak herds are listed in Table 5.7. In the Ahiak herd, calf:cow ratios were high in 2008 as in other herds, but lower in spring 2009. These are the first spring composition surveys for this herd. Spring calf:cow ratios were recorded for the Bluenose-East herd in 2001, 2004, 2007, 2008 and 2009. Calf:cow ratios in these years were generally similar to those in the

Bathurst herd (Figure 5.7) or slightly higher. However, spring recruitment surveys were not carried out annually in this herd, so we do not know if the exceptionally low calf:cow ratios in the Bathurst herd in 2005 and 2006 also occurred in the Bluenose-East herd.

Table 5.7. Summary of spring (March/April) composition surveys for the Bluenose-East and Ahiak herds. Bluenose-East data from R. Popko, ENR Sahtu region (unpublished data); Ahiak data A. Kelly, ENR South Slave region (unpublished data). The % calves values do not always match the calf:cow ratio because variable proportions of bulls were recorded.

Herd	Year	Total caribou classified	Calves /100 cows	% calves in sample
Bluenose-East	2001	6,680	25.1	28.7
Bluenose-East	2004	5,517	51.6	29.3
Bluenose-East	2007	5,419	48.7	18.7
Bluenose-East	2008	5,604	48.3	27.2
Bluenose-East	2009	6,110	38.4	23.4
Ahiak	2008	11,163	48.3	25.8
Ahiak	2009	6,502	31.0	16.9

Table 5.7. Summary of spring (March/April) composition surveys for the Bluenose-East and Ahiak herds. Bluenose-East data from R. Popko, ENR Sahtu region (unpublished data); Ahiak data A. Kelly, ENR South Slave region (unpublished data). The % calves values do not always match the calf:cow ratio because variable proportions of bulls were recorded.

Fall composition surveys were carried out for the Bathurst herd in 2006, 2007 and 2008 (Table 5.8). These surveys are a necessary part of calculating a herd size estimate if June calving photo surveys are used, as very few bulls are found on the calving grounds. Carried out during the rut, these surveys provide the best opportunity to estimate the sex ratio, because all sex and age classes are mixed.

Table 5.8. Summary of fall (October) composition surveys, Bathurst herd 2006-2008, Bluenose-East herd 2008-2009, Bluenose-West herd 2009, and Ahiak herd 2009 (ENR unpublished data).

Herd	Year	Total caribou classified	Total groups classified	Calves /100 cows	% calves in sample	Bulls/100 cows
Bathurst	2006	5,610	69	40.2	22.7	36.2
Bathurst	2007	7,283	148	55.2	29.3	30.6
Bathurst	2008	3,532	42	31.9	18.7	38.3
Bluenose -West	2009	4,620	147	51.9	23.4	69.8
Bluenose -East	2009	4,531	79	46.0	24.4	42.9
Ahiak	2009	3,772	41	46.4	23.2	53.8

The sex ratio for the Bathurst herd was between 30.6 and 38.3 bulls: 100 cows between 2006 and 2008 (Table 5.8). These sex ratios are lower than was found in barren-ground caribou herds reviewed by Bergerud (2000) where ratios of about 50:100 were more common as an average value. Heard (1985) found bull:cow ratios over 60:100 in increasing NWT herds. A recent fall survey (Oct. 2009) of the neighboring Bluenose-East herd showed a sex ratio of 42.9:100 (Table 5.8). A fall count for the Bluenose-West herd showed a higher value of 69.8 bulls:100 cows, and a fall count of the Ahiak herd showed a sex ratio of 53.8:100. The low sex ratio in the

Bathurst herd may in part reflect a declining natural trend in the early 2000s; males almost always have higher mortality rates than females, especially if environmental conditions are poor (Bergerud 2000). In addition, there has been a substantial harvest by outfitters from the Bathurst herd (see section 5.8), a poorly documented aboriginal fall bull harvest, and a limited bull harvest by resident hunters. Mapped collar information suggests that the 2009 outfitter harvest was at least half from the Bluenose-East herd and some of the outfitter harvest in other years was likely also from this herd (section 5.8).

5.5 Pregnancy rate and body condition (BE & JA)

A separate report by B. Elkin and co-authors provides an overview of 4 field collections of Bathurst caribou in September 2007, March 2008, September 2008 and April 2009. These were carried out to assess condition, pregnancy rate (in winter), health, and contaminant status of this herd. Here we have extracted portions of that report, focusing on cow body mass, condition (back fat and hunter condition score), and pregnancy rate, as the values most likely to affect population trend. Condition of caribou cows in the fall is strongly related to likelihood of pregnancy (Cameron et al. 1993, Russell et al. 1998, Kofinas et al. 2002) and reflects the accumulated nutrition of the cow over the summer and fall.

Samples were collected as follows:

- 1) Mackay Lake, September 7-13, 2007. Samples and measurements were taken from caribou harvested during a fall hunt by the Yellowknives Dene. A total of 51 caribou were sampled (17 adult cows, 17 adult bulls, 3 yearlings, 14 calves).
- 2) Beaverlodge Lake, March 11-14, 2008. Samples and measurements were taken from 38 caribou harvested in conjunction with Tlicho hunters (26 adult cows, 2 adult bulls, 1 yearling, 9 calves).
- 3) Lac de Gras, September 9-11, 2008. Samples and measurement were taken from 31 caribou harvested caribou in conjunction with hunters from the Yellowknives Dene (12 adult cows, 13 adult males, 1 yearling, 5 calves).
- 4) Strachan Lake, April 4-6, 2009. Samples and measurements were taken from caribou harvested in conjunction with Tlicho hunters from Gameti. A total of 30 caribou were sampled (28 adult cows, 1 adult bull, 1 calf).

Measurements of body size and mass included full body weight, carcass weight, body length, chest girth, and foot length. Age was determined for each caribou using both a field estimate based on size & appearance, tooth wear, and laboratory tooth cementum analysis. Overall fatness/body condition were assessed by several methods, including depth of back fat, kidney fat weight, percent of fat in the bone marrow, and visual condition scores assessed by hunters (1, skinny, 2 not so fat, 3 fat, 4 very fat). Cows estimated or aged as at least 3 years old were assessed as adults in this evaluation. In general, hunters took caribou as they were available and we believe that the sampled animals were a fairly unbiased sample of the herd in that area.

Back Fat: In September 2007, back fat in cows averaged 3.75 mm (range 0 - 15), with greater fatness recorded in September 2008, with an average of 29.8 mm (range 25-39). In March 2008 the cows averaged 12.5mm of back fat (range 1.5-26) and 6.6 mm (range trace – 23) in April 2009.

Body Mass: In September 2007, cow body mass averaged 86.3 kg (range 71-106), and was higher in September 2008 at an average of 94.9 kg (range 77-116). In March 2008, average cow body mass was 85.9 kg (range 77-99) and a similar body mass of 84.2 kg (range 67-106) was found in April 2009.

Hunter Condition Score: Condition of cows was rated by hunters in March 2008, September 2008, and April 2009, but not in September 2007. The average score (1-4) was 2.9 in March 2008, 3.4 in September 2008, and 2.6 in April 2009. Numbers of cows rated in each category for the three collections are shown in Fig. 5.8.

Figure 5.8. Percentages of cows rated by hunters on a 4-point scale (1 skinny, 2 not so fat, 3 fat, and 4 very fat) in assessing Bathurst caribou cows during three seasonal collections 2007-2009.

Pregnancy rate: In March 2008, 26 of 26 adult cows assessed as part of the condition and health assessment were pregnant. This field work was carried out at a camp near Beaverlodge Lake, north of Gameti. In addition, a further 35 of 36 cows were pregnant, from a hunt carried out about a week later by hunters in the Bathurst range (E. Evans pers. comm. March 2008) at a different location 160 km away (near Indin Lake) but also in an area with wintering Bathurst caribou. In April 2009, 25 of 28 cows were pregnant during that collection. Pregnancy rates in the two late-winter collections in 2008 and 2009 were added to Figure 5.9, which shows late-winter pregnancy rates in 6 previous condition and health studies of this herd. The lowest pregnancy rate recorded among these Bathurst collections was in March 1991 (60%), with other values generally between 80 and 100%.

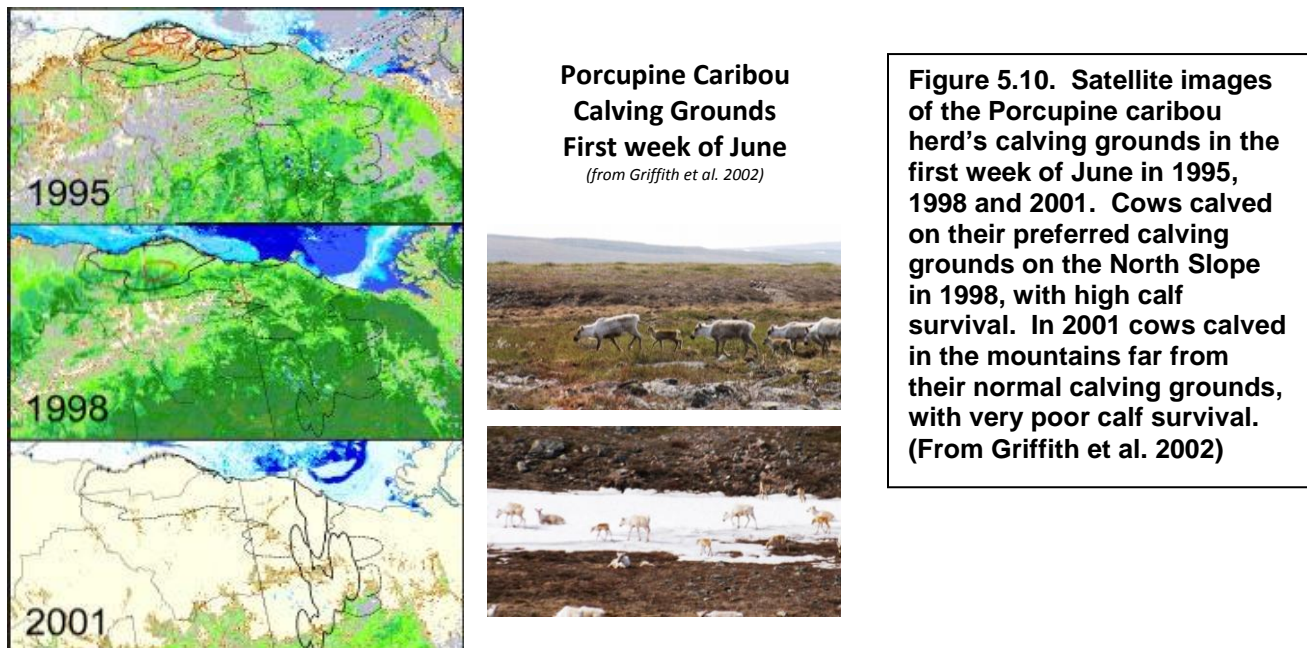

Figure 5.9. Pregnancy rates in Bathurst adult caribou cows assessed in late-winter hunts between 1990 and 2009.

Overall, the condition and pregnancy information for the Bathurst herd in 2007-2009, while based on limited sample numbers, suggests that the cows were in good or very good shape, with high pregnancy rates. Body mass and condition recorded by Dauphine (1976) for Qamanirjuaq caribou in the 1970's were generally below the values recorded in these Bathurst collections. Body mass in autumn has been found to correlate strongly with pregnancy rate in caribou (Cameron et al. 1993, Russell et al. 1998), and the average Bathurst September body masses of 86.3 kg in 2007 and 94.9 kg in September 2008 should have translated to 80 % and 90% pregnancy rates, respectively, in late winter 2008 and 2009, based on the relationships in those two papers. Actual pregnancy rates were 100% in March 2008 and 89% in April 2009. The scores from hunters for three collections also indicate that the cows were generally in good if not exceptional condition.

5.6 Environmental trends (JA)

Weather can affect barren-ground caribou in a variety of ways. A late spring may mean that cows calve far from their preferred familiar calving grounds and summer calf survival is poor (Griffith et al. 2002), summer forage may vary in quantity and quality (Chen et al. 2009a), a hot dry summer may mean more fires on the winter range (Chen et al. 2009b) or severe insect harassment in July (Helle and Tarvainen 1984), and above-freezing temperatures and rain may mean ice layers that make it difficult for caribou to reach their preferred winter forages (Chen et al. 2009b). We do not propose in this report to review this large subject; rather, we have excerpted much of this section from a report by Gunn and Poole (2009) titled “Environmental Trends across the range of the Bathurst Caribou Herd and timing of the arrival of cows on their calving ground 1996-2009” with permission of the authors. This report in turn borrowed results from two papers by Chen et al. (2009a,b) on environmental trends on the Bathurst herd’s seasonal ranges. These three reports are included as supporting documents that provide greater detail on this subject.

The effects of environmental trends on caribou or other wildlife are difficult to evaluate because there is substantial variation at various temporal and spatial scales. One particular winter may be colder than average, but the trend over a 5 or 10 year period may be warmer winters. Some regions may experience an unusual rain in December or January, but the effect may be limited in extent. The overall trends in the Bathurst herd's range in recent years have been warming temperatures and increases in precipitation, but less precipitation as snow. The plant growing season has grown longer and plant biomass has increased, but forage quality has shown a slight but non-significant declining trend. Snowmelt on the calving ground was annually variable; 1998 and 2008 were two early snowmelt years, and 2001 and 2005 were two late years. There has been a reduction in lichen-rich habitats on the winter range, largely as a result of forest fires. The period from 2006 to 2009 has not shown any major changes in environmental trends from the preceding years in the early 2000s. High pregnancy rates and good body condition in Bathurst cows 2007-2009 (see preceding section 5.4), and higher spring calf:cow ratios (section 5.3) than in the early 2000s suggest that environmental conditions for Bathurst caribou in 2007-2009 were improved over the early 2000s.

5.6.1 Trends for the Bathurst calving grounds and summer range

Figure 5.11. Green foliage biomass during pre-calving (21–31 May), peak calving (1–10 June), and post-calving (11–30 June) on the calving ground of the Bathurst caribou herd, 1985–2006 (Chen et al. 2009 In prep. a).

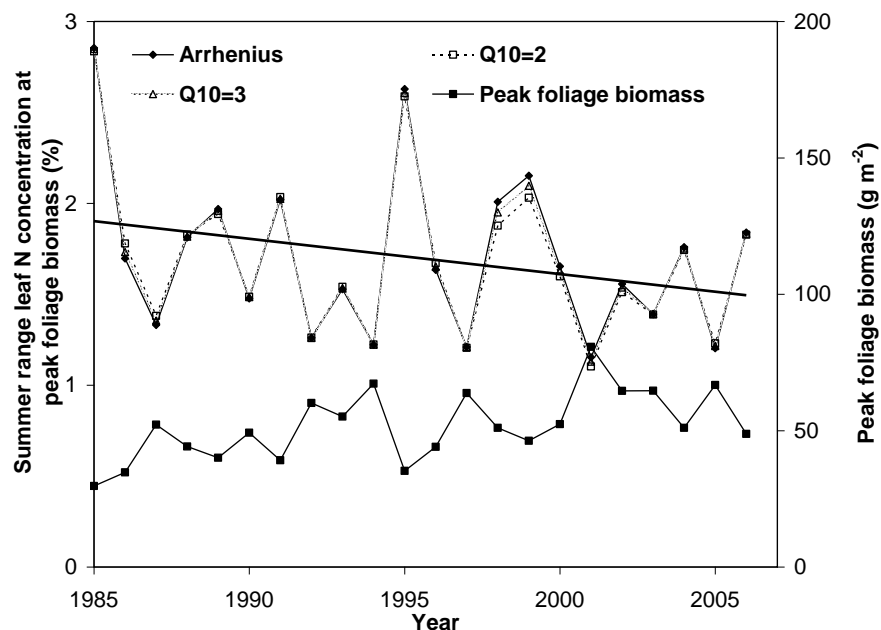

Figure 5.12. Summer forage availability indicator (foliage biomass), defined as the average foliage biomass from 11 June to 30 September in the summer range, for the Bathurst caribou herd, 1985–2006. The straight line represents temporal trend with $R^2 = 0.29$, $F = 8.3$, $P = 0.009$, and $n = 22$ (from Chen et al. 2009 In prep. a).

Based on satellite imagery for 1985–2006, there was essentially no green foliage biomass during the pre-calving period (21–31 May; Figure 5.11). During 1–10 June, only 3 of the 22 years had green foliage biomass > 0.4 grams (1991, 1994, and 1998). The levels of green biomass during post-calving (11–30 June) varied annually and appeared to increase 55% from 1985 to 2006, but the high annual variation meant that the trend was not significant. The amount of green biomass correlates with the start date of plant growth – biomass was less when the date was later. The lichen vegetation classes decreased significantly from 1990 to 2000, from 44% to 22% of the total calving ground area, possibly due to shrub plants replacing lichens. The decrease in lichens relative to increase in vascular plants (Cornelissen et al. 2001) possibly is a result of competition for nitrogen, as nitrogen mineralization increases with warming temperatures (Epstein et al. 2004).

On the summer range (11 Jun–20 Sep), mean foliage biomass showed a significant increasing trend despite high levels of annual variability (Figure 5.12). The longer the growing season, the greater the amount of biomass. However, an indicator calculated for forage quality, leaf nitrogen, decreased during 1985–1996, although the trend was not significant as annual variation was high. Leaf nitrogen was also negatively correlated with growing season length.

Insects can affect caribou energy balance in caribou by interfering with feeding and by causing the caribou to run, walk and stand more than normal (Helle and Tarvainen 1984). The late 1970s and early 1980s marked the beginning of a global temperature increase. Based on this, the period of 1957–2005 was divided into 2 groups: 1957–1981, and 1982–2005. The number of “High” oestrid ratings was significantly greater in the 1982–2005 grouping than during the earlier time period ($\chi^2 = 18.68$, $df = 1$, $P < 0.01$; Figure 5.13).

Figure 5.13. Trend line and annual scores oestrid fly harassment (scored as 1 for low, 2 for moderate and 3 for high) based on 1957–2005 weather records for Contwoyto Lake, NU (from Gunn In prep.).

5.6.2 Environmental trends for the winter ranges

The area of lichen ranges as indexed by mature forests declined between 1959 and 2006, likely in part due to periodic forest fires (Figure 5.14). The area of forest burnt was significantly related to mean 1 June–30

September temperatures over the winter range of the Bathurst herd during 1959–2006, and those temperatures have increased (Chen et al. In prep. 2009b).

Snow conditions influence the availability of forage for caribou. Two indicators are the annual maximum snow depth and ice content of the snow (Chen et al. In prep. 2009b). A combined approach using data from the four weather stations on the Bathurst herd's winter range and remote sensing was necessary as snow conditions vary across the winter range. Maximum snow depth relates to October and April temperatures: a warmer October usually has less snow depth at the end of October, which contributed to less annual maximum snow depth. The trend toward warmer fall and late winter air temperatures reduced the annual maximum snow depth but increased the probability of thaw freeze events. The mean ice content in snow indicator may be caused by thaw-freeze events and rain on snow events and varies considerably between years and weather stations (1963–2006; Figure 5.15). The percent of years in which ice content in snow was >10 mm water equivalent increased from 14 to 43%, during 1960s to 2000–2006, respectively. Overall, the ice in snow indicator had a significant positive relationship with April–October air temperature, indicating an increase in “hard” snow or icy crust in the snowpack under a warming climate (Chen et al. In prep. b).

The average of snow presence/absence during pre-calving migration (16 April–15 June) based on AVHRR imagery was annually variable, which prevents determining if there was a trend from 1982 to 2006 (Figure 5.16). Snow presence or absence during pre-calving migration was negatively correlated with 16 April–15 June mean air temperature during 1982–2006.

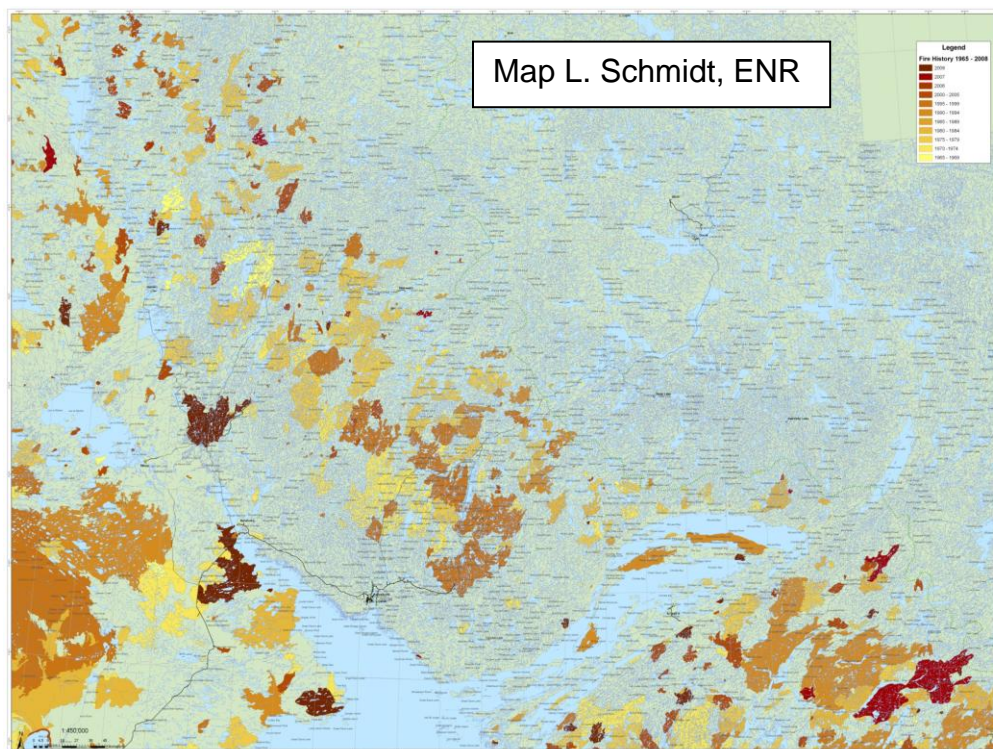

Figure 5.14. Map of fire history in the North Slave region of the Northwest Territories. Burns of different colours identify fires of various ages. The Bathurst herd's winter range covers a large area north and east of Great Slave Lake.

On average, snowmelt took 20 and 23 days for snow cover at the Ekati mine site to change from 100% to 50% cover, and from 50% to 0% cover, respectively (Table 5.9, Figure 5.17). Year 2009 was noteworthy in that early snowmelt was late as the 100–50% snow cover was the latest date recorded and took 36 days, but remaining snow disappeared quickly within five days, although not until 15 June. The rating of the years for whether snowmelt was early or late at Ekati generally correlated with the percentage of snow cover on the

winter range (Chen et al. In prep. b) during the duration of pre-calving migration (Table 5.9). Years with lesser or greater snow cover had earlier or later snowmelt, respectively. On the calving ground (150 km north-northeast of Ekati) Croft (pers. comm. 2009) estimated that snow cover across the entire calving area in June 2009 was 50–80%, but once it began, snow-melt was exceptionally fast. Years 2007 and 2008 were actually a bit later as snow cover was consistently about 80% over the calving ground when the systematic reconnaissance surveys were done during the peak of calving for those 2 years.

Figure 5.15. Mean ice content in snow (ICIS) for the winter range of the Bathurst caribou herd from 1963 to 2006, for Yellowknife, Reliance, Rae Lakes, and Uranium City climate stations. The straight lines represent temporal trends: for $ICIS_{rain}$ $y = 0.0225x - 44.065$, $R^2 = 0.06$, $F = 2.86$, $P = 0.1$, and $n = 44$; for $ICIS_{thaw}$ $y = 0.0544x - 100.4$, $R^2 = 0.06$, $F = 2.59$, $P = 0.12$, and $n = 44$; and for $ICIS$ $y = 0.0769x - 144.48$, $R^2 = 0.08$, $F = 3.7$, $P = 0.06$, and $n = 44$ (From Chen et al. In prep. b).

Figure 5.16. Percent snow cover averaged over the Bathurst caribou habitat during 16 April–15 June from 1982–2006, derived from AVHRR Polar Pathfinder data. The straight line represents the temporal trend: $R^2 = 0.05$, $F = 1.1$, $P = 0.3$, $n = 25$ (from Chen et al. In prep. b).

Table 5.9. Timing of spring snowmelt in the Ekati study area, 1997 to 2009 (BHP Billiton 2009; D. Abernathy, BHP Billiton, pers. comm.) and annual percentage snow cover averaged from 16 April–15 June (data from W. Chen, pers. comm. 2009)

Year	100%	50%	0%	General timing	Percent snow cover	No. of days 100–0% snow cover
1997	16 May	30 May	30 Jun	Late	74	45
1998	16 Apr	11 May	28 May	Early	40	42
1999	27 Apr	29 May	20 Jun	Late	71	54
2000	3 May	23 May	15 Jun	Average	65	43
2001	21 May	2 Jun	20 Jun	Late	74	30
2002	1 May	24 May	14 Jun	Average	80	44
2003	2 May	-	28 Jun	Average ¹	66	57
2004	13 May	30 May	26 Jun	Late	90	44
2005	22 May	29 May ²	25 Jun	Late	68	34
2006	20 Apr	7 May ³	16 Jun	Early	48	57
2007	17 Apr ⁴	-	12 Jun	Average		58
2008	17 Apr	2 May	25 May	Early		38
2009	5 May	10 Jun	15 Jun	Late		41
Mean	2 May	23 May	16 Jun			45

¹ Indications from the survey were that overall snowmelt was average

² Snow cover was 60%.

³ Snow cover was 40%.

⁴ Snow cover was 95%.

Figure 5.17. Number of days elapsed between the last day of 100% snow cover and the first day of 50% snow cover, and between 50% snow cover and 0% snow cover in the Ekati study area, 1997 to 2009 (calculated from Table 5.9).

5.6.3 Peak of calving and entry of satellite collared cows into the calving area

Dates of peak calving based on the movement data shifted about four days between the mid to late 1990s (the first few years of the collaring program) to the years after 1999 (Table 5.10). The movement patterns indicated

peak of calving in 2005 averaged about six days later than peak of calving during most of the remainder of the 2000s. With the exception of 2005, the peak of calving has remained stable (8–14 June) during the 2000s. The June 2009 calving photos survey provides an indication that the shift toward later calving may be reversing. The photo plane flew on June 8 and 9; a survey crew on those days recorded composition of calving caribou groups on these days and over half the cows had given birth by that point.

Overall mean dates for satellite-collared cows crossing the outer and inner distance circles surrounding the centre of the Bathurst caribou calving ground were 21 May and 26 May, respectively. The trend in timing of arrival in the calving area was later between 1996 and 2005 (mainly due to the two lowest years being 1996 and 1998), but this trend does not appear to have continued over the past four years (Figure 5.18). Mean dates for crossing the outer and inner distances in 2009 were 23 May and 26 May, respectively. There appears to be a pattern for alternate earlier and later years for six years then after 2003 the pattern changed from an alternate year switch.

Figure 5.18. Mean (SE) dates of crossing of the outer (122 km radius) and inner (61 km radius) distance circles surrounding the centre of the Bathurst caribou herd calving grounds, 1996–2009.

With the exception of 2005, in all years only 1–2 collared caribou either did not enter the peak calving grounds or entered after the 10 June cut-off (Table 5.10). In all but four years this represented <8% of collared animals; on average 92% ($\pm 2.9\%$ SE) of collared caribou entered the peak calving grounds prior to 10 June. Year 2005 was particularly unusual, as seven caribou (39%) entered the peak calving grounds late (13–30 June). These cows may not have been pregnant. Only one collared caribou did not enter the peak calving grounds in 2009; this animal stayed near the south end of Contwoyto Lake during early to mid-June, within the area covered by reconnaissance flights for the 2009 census (J. Nishi, pers. comm.). Observations in the field on the June 2009 survey suggested that the peak of calving had shifted slightly earlier in June. The photo-plane flew on June 8 and 9, while a helicopter-based crew carried out a composition survey. By June 8 and 9 over half the cows had a calf at heel, indicating that the peak of calving was likely June 6–9.

Table 5.10. Peak of calving for the Bathurst herd and proportion of collared caribou that reached the peak calving grounds (CG) by 10 June, 1996-2009, as determined from satellite collar data (Gunn et al. 2008, and updated to 2009). Primarily GPS/satellite collar data were used in 2009. Determination of calving was based on changes in movement rates.

Year	Peak of calving	No. of caribou available for assessment	No. of caribou (%) that reached the CG by 10 Jun	Comments
1996	4-10 Jun	9	9 (100)	
1997	4-10 Jun	7	7 (100)	
1998	4-10 Jun	10	10 (100)	
1999	8-14 Jun	14	13 (93)	1 never entered CG
2000	8-14 Jun	13	12 (92)	1 never entered CG
2001	8-14 Jun	13	11 (85)	1 never entered CG; 1 late arrival; did not calve
2002	8-14 Jun	11	11 (100)	
2003	8-14 Jun	12	11 (92)	1 late arrival; did not calve
2004	8-14 Jun	6	5 (83)	1 late arrival; did not calve
2005	14-20 Jun	18	11 (61)	7 late arrivals; 2 calved, 5 did not
2006	8-14 Jun	14	14 (100)	
2007	8-14 Jun	19	19 (100)	
2008	7-10 Jun	12	10 (83)	2 late arrivals; did not calve
2009	6-9 Jun	13	12 (93)	1 never entered CG

5.6.4 Indirect measures of environmental trends

Overall, the trends in environmental indicators point to changes over time on the calving, summer and winter ranges of the Bathurst herd, but there do not appear to have been major changes since 2006 that would identify a reason for the accelerated decline of the Bathurst herd after 2006. The higher recruitment, good condition of the cows (sections 5.4 and 5.5) and tendency in 2009 toward an earlier peak of calving, all suggest that the Bathurst herd was experiencing improved environmental conditions in 2007-2009 over 2000-2006. High calf survival is usually correlated with high adult natural survival rates in adult caribou (Bergerud 2000).

5.7 Age structure (JA & JB)

In the Bathurst herd, years of low calf survival (2001 – 2006) led to changes in the herd's age structure. In particular the 2005 cohort was small as calf survival was especially low, and other cohorts from that period will also have low representation in the herd. Weak cohorts and a shift in age structure could influence both the decline and potential recovery of the Bathurst herd.

For migratory tundra caribou, changes in age structure are relatively little discussed in the context of changes in abundance. This is partly because age specific data are often lacking or sample size is low. Yet in other long-lived mammals, the importance of age structure relative to census data for detecting declines is well-recognized, for example, in marine mammals (Holmes and York 2003) and in other large-bodied herbivores (Festa-Bianchet et al. 2003, Coulson et al. 2004). Coulson et al. (2004) commented that cohort performance is under-estimated as a factor in demography. They reported that a deductive construction using density-

dependent age- and sex-specific survival and recruitment functions with climate enabled 90% of the variation in population growth of Soay sheep to be explained. Their model captured important, persistent differences in the contribution of different cohorts to the population dynamics of the sheep.

The role of weak cohorts rather than a sustained trend in low recruitment was a factor in the decline of the Alaskan Nelchina herd (Eberhardt and Pitcher 1992). These authors described age structure reconstructed from 2800 hunter-contributed mandibles (1954-1971). The reconstruction revealed 3 years (1964-67) when recruitment was extremely low and those weak cohorts were a driving factor in the herd's decline.

The second aspect of age structure apart from weak cohorts is that reduced recruitment in a sequence of cohorts will shift the overall age structure from middle-aged to older females. Bergerud et al. (2008) used mandibles from hunters and found that in the George River herd, the mean age of females increased from the increasing phase to the decline phase (1974-1993) by 13 months (Bergerud et al. 2008). One effect of a shift to older females is older females having reduced condition and greater frequency of breeding pauses. A second effect is that in large-bodied ungulates, survival decreases with senescence. For example, estimates of adult survival have to include senescence to avoid serious errors (Eberhardt 1985).

Figure 5.19. Distribution of ages at death of female caribou from condition studies in 1992 and 2008. The herd was at high numbers and stable/declining slightly in 1992 and had a greater representation of young cows than in 2008.

Bathurst data

Female age specific-survival data with ages based on cementum annuli were available through the CARMA database for 1990 (12); 1991 (50); 1992 (35) through D. Heard and M. Williams (details in Gunn et al. 2005). A second dataset is available from 2007-08 collections (data from B. Elkin and B. Croft, ENR, September 2009). In September 2007 and March 2008, year classes were available for 44 females (data from September 2008 and April 2009 had not been received).

The early 1990s data were obtained when the Bathurst herd was at its peak and suggest a small shift in age classes toward an older age structure in the late 2000s (Figure 5.19). Interpretation is limited by small sample sizes in the year classes, especially the first three cohorts. Further analyses could be considered when the 2008 and 2009 age assignments are available. With overall cow mortality rates estimated at 32 % in 2009

(see section 6.2), it is likely that few cows reached advanced ages at which poor condition might affect survival and reproduction.

One of the outcomes of the OLS modeling (section 6) was a re-construction of the Bathurst herd's likely age structure from 1986 to 2009. This is not based on empirical data but does also suggest that by 2009, the age structure of the herd's cows would have a high proportion of young cows from the increased recruitment 2007-2009, and a higher representation of older cows than in the 1980s. The large proportion of very young females could mean a delayed recovery (if cow mortality is reduced) as these females would need another year or two to reach breeding age. If many older females had a lower reproductive output or lower survival, this could have contributed slightly to the herd's decline in the late 2000s.

Figure 5.20: Trends in (modeled) estimated proportion of age classes (females only) based on reconstruction of age classes. Estimates are from the most supported OLS model. Caribou aged 4-9 are usually considered to have the highest level of reproductive output (fecundity and calf survival).

5.8 Hunter harvest (BC & JA)

Accurate and up-to-date harvest reporting is one of the key information gaps for the Bathurst herd, and for other NWT caribou herds, particularly when the herds are declining and at low numbers. Some of these herds range over large areas and harvest from all sources must be considered. In this section we report the information that is available on harvest of Bathurst caribou.

5.8.1 Aboriginal harvest of Bathurst caribou

Reporting of aboriginal harvest of barren-ground caribou in the NWT has varied over time, although all estimates and reported data indicate that it has been the main part of the harvest for this herd. In the Inuvialuit, Gwich'in and Sahtu Settlement Areas, harvest studies mandated by land claims have produced 5 or more years of information on aboriginal harvest of caribou and other wildlife. However, those harvest studies ended several years ago and harvest information since then has been incomplete. The WRRB is planning a harvest study for the Tlicho Settlement Area, likely to begin in 2010.

A study of aboriginal harvest in the Dogrib (Tlicho) region was carried out for 6 years from 1988 to 1993 (Table 5.11). We assume that most of this harvest was Bathurst caribou, as recent satellite collar studies indicate some overlap in winter with Bluenose-East caribou to the west and Ahiak caribou to the east. In the late 1980s and early 1990s the Bathurst herd was estimated at about 350,000. The average number of Bathurst caribou taken annually was estimated at 15,864, with slightly more than half (8,380) being cows. This would be about 4.5% of a herd of 350,000. Some observers have suggested that the numbers are substantial over-estimates, and that the harvest in more recent years was well below these totals (pers. comm. Earl Evans, Ft. Smith, 2009).

Year	Number of bulls taken	Number of cows taken	Total caribou taken
1988	4,606	3,318	7,924
1989	3,855	4,730	8,585
1990	8,970	8,450	17,220
1991	10,073	11,626	21,699
1992	9,685	9,046	18,731
1993	7,712	13,107	20,819

Table 5.11. Numbers of caribou hunted annually 1988-1993 in the Dogrib region from the Bathurst herd, based on the Dogrib Harvest Study. From Boulanger and Gunn (2008).

The North Slave ENR regional office in collaboration with the Tli Cho Land Protection Department has operated a check-station on the winter road to Gameti and Wekweeti in the last two winters, to monitor the caribou harvest. In addition, hunters from Wha Ti, Gameti and Wekweeti were interviewed to determine numbers of caribou harvested during the two years of the project from hunters of those three communities (figure 5.21a and 5.21b). The totals reported in the last two winters were 1690 and 2712 caribou respectively, with more than half being cows (B. Croft and T. J. Rabesca, ENR, unpublished data). However, these totals are under-estimates for the following reasons:

- (1) Not all active hunters were interviewed each year and no correction or adjustment factor was applied to account for missing hunters.
- (2) Some of the hunters interviewed very likely under reported their harvest for fear of consequences to their subsistence harvest rights.
- (3) Some hunters did not recall exact numbers of caribou harvested given the time lag between the harvest and the interview date; this also applied to the sex ratio in the harvest.
- (4) There was a high turnover rate of staff at the check station, at times leaving the station unattended when south-bound hunters were driving by.
- (5) Some hunters did not stop to report their harvest at the check station.

(6) Wounding losses would not be picked up by the check-station or the interviews.

Doubling the results of this reporting project, as suggested by wildlife officers in the field, would add up to 3,380 - 5424 caribou, primarily cows, and the total winter harvest may have been higher in some years.

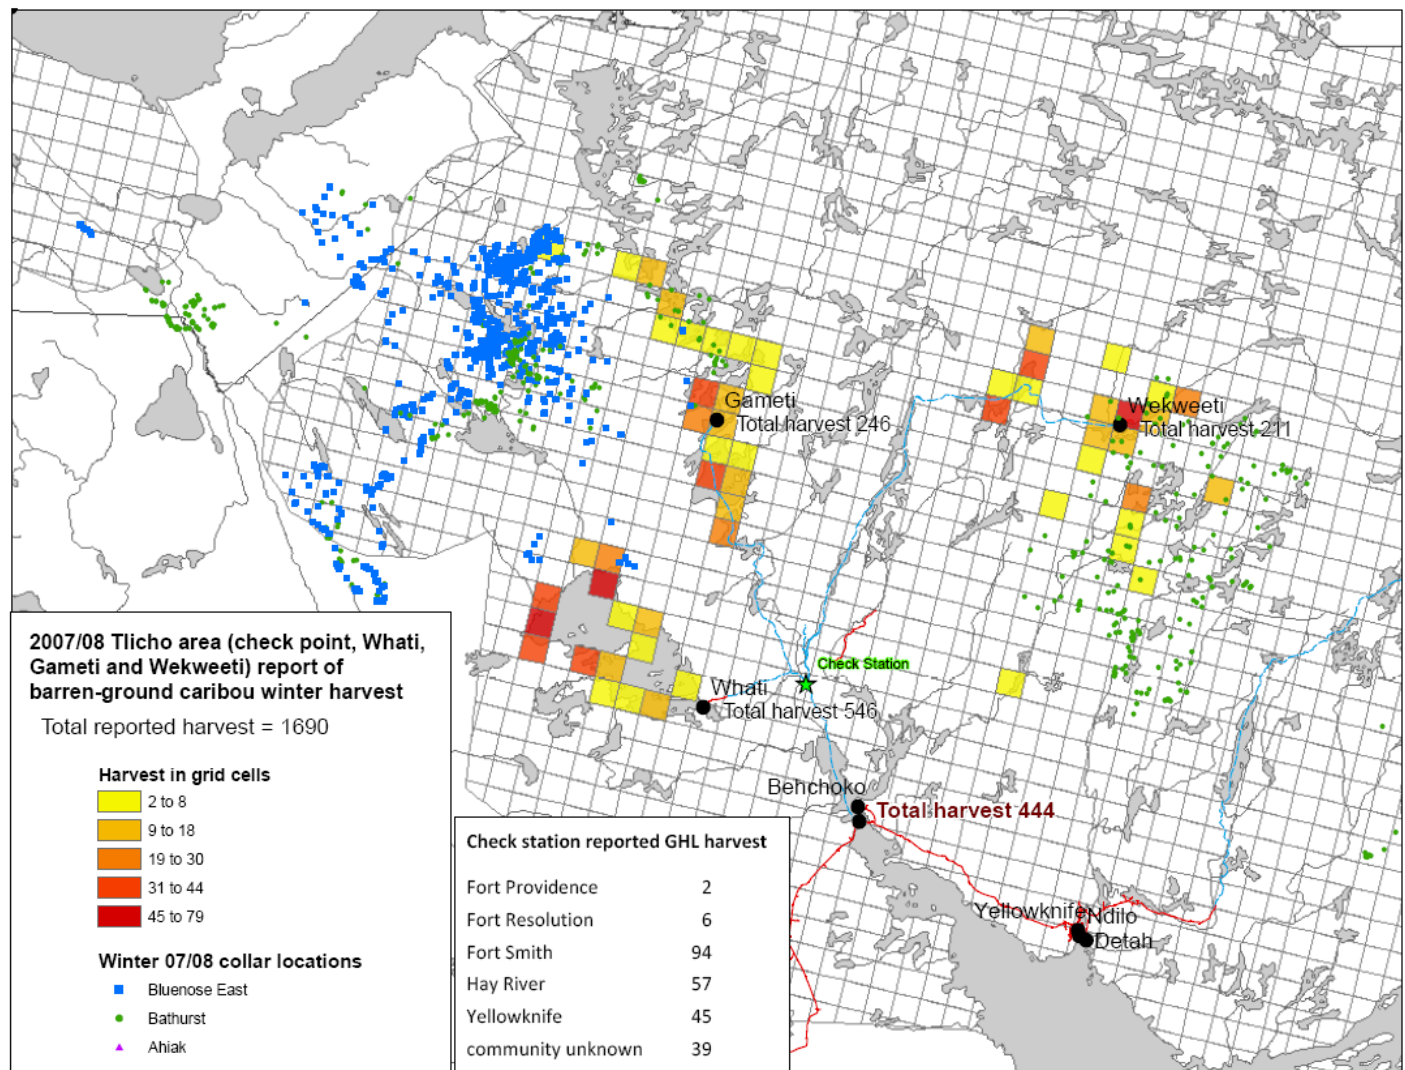

Figure 5.21a. Map showing harvest of caribou in winter 2007/2008 near Tlicho communities north of Yellowknife. The squares are 10x10km blocks and the colour scheme shows where greater and lesser numbers of caribou were taken. Blue dots are winter satellite collar locations of Bluenose-East caribou and green dots are Bathurst satellite collar locations.

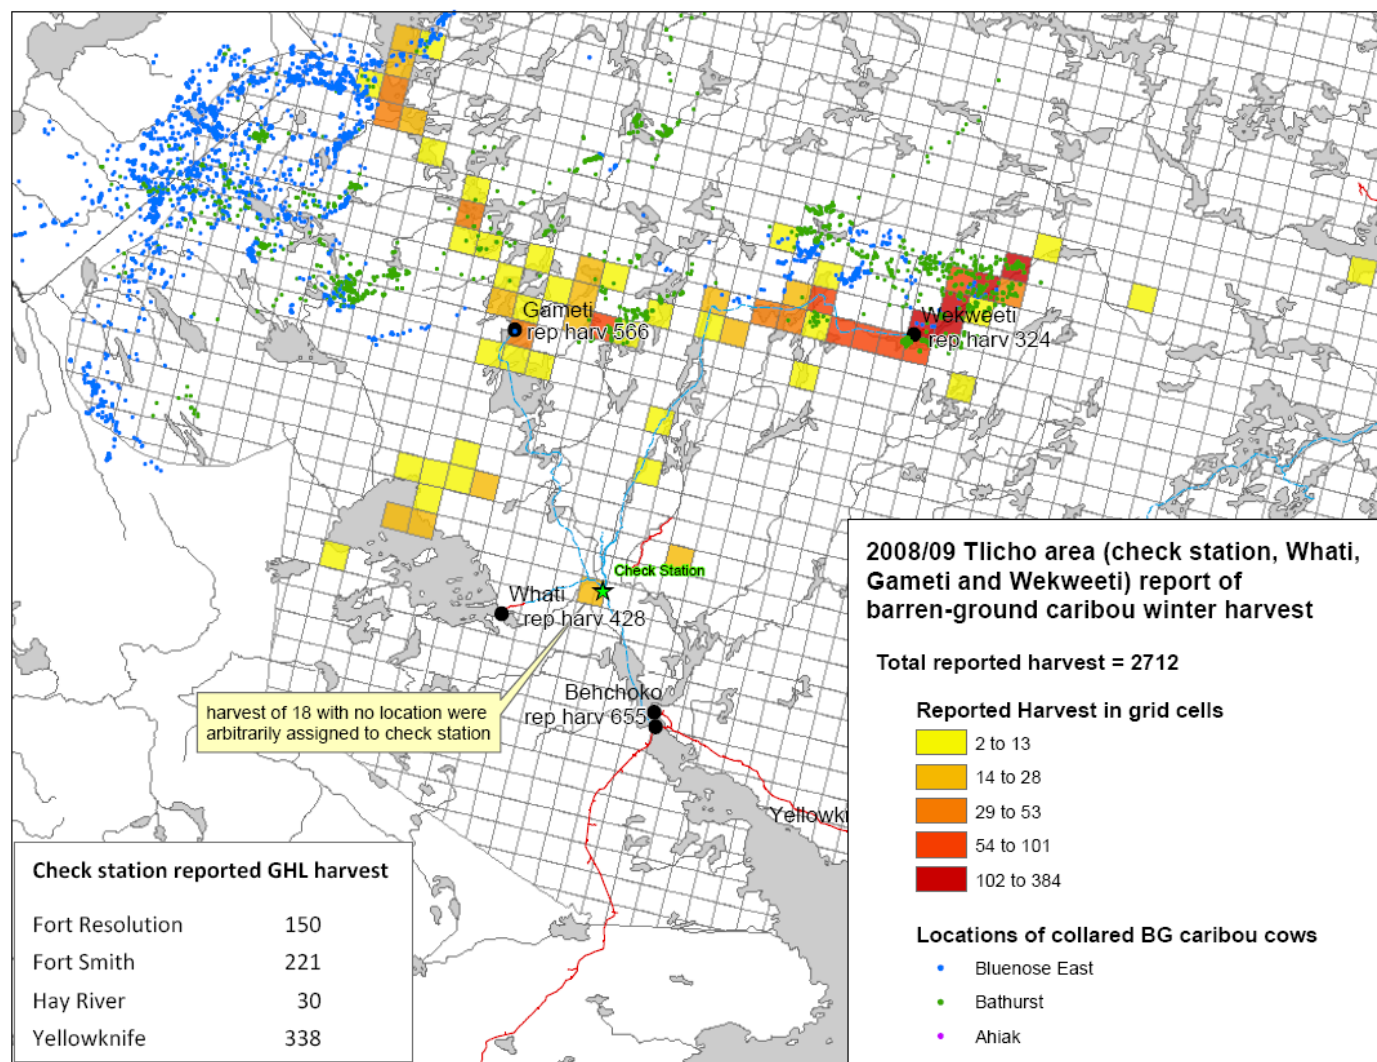

Figure 5.21b. Map showing harvest of caribou in winter 2008/2009 near Tlicho communities north of Yellowknife. The squares are 10x10km blocks and the colour scheme shows where greater and lesser numbers of caribou were taken. Blue dots are winter satellite collar locations of Bluenose-East caribou and green dots are Bathurst satellite collar locations.

The population modeling by J. Boulanger provided an opportunity to get an approximate estimate of the cow harvest (see Section 6.2) by back-calculation from survival rates. We emphasize that this is a model projection, not an empirical estimate. The model estimated cow survival rate at 0.86 in the 1980s when the effects of harvest were very low relative to herd size. If this survival rate is used as an estimate of natural cow survival, then the difference between 0.86 and the model-estimated survival rate in 2008-2009 of 0.68 should be roughly equal to hunting mortality of cows. This translates approximately to an annual harvest of 5000 cows (section 6.2). This estimate is based on the assumption that relative natural mortality levels, movements and other factors affecting apparent survival did not change appreciably over the time period studied. A similar back-calculation by C. Nicolson using the Bathurst Caribou Calculator suggested that the estimated annual harvest included about 4,000-5,000 cows. In some winters (but not in recent years) satellite collared Bathurst caribou have wintered in northern Saskatchewan and aboriginal hunters from communities in the northern part of the province likely took some Bathurst caribou. The numbers of caribou taken by hunters from those communities are not well documented.

Table 5.12 was reported by Nesbitt and Adamczewski (2009) as a summary of how aboriginal hunting practices have changed in the last 30-40 years, based on observations by W. Bayha, J. Rabesca, M. Rabesca, D. Beaulieu and others at a workshop on caribou population models and hunter harvest in May 2009 in Yellowknife. During earlier periods of caribou scarcity, hunters shifted to other game or fish, and some regions remained remote. This most likely allowed caribou herds to recover. In the present day, however, access during winter is much greater due to winter roads to the communities and diamond mines north of Yellowknife, and there are many more trucks and skidoos than in the 1970's when caribou were last at low numbers. Hunters from many communities north and south of Great Slave Lake have hunted the Bathurst herd in recent years.

Table 5.12. Comparison of traditional hunting practices and present-day aboriginal hunting in the NWT. From Nesbitt and Adamczewski (2009).

<i>Traditional hunting</i>	<i>Current hunting</i>
Done with snowshoes / dog-team / slower snowmobiles with small wooden toboggans	Fast, widetrack snowmobiles with large teflon and fiberglass toboggans. People even hunt from trucks and vans on the winter roads.
Good organization / Community / Social event	Many small groups / often strangers
Open scope. Less accuracy. Fewer animals taken	High powered rifles with scopes – shoot from a distance; shoot many quickly
Taking your time	Done quickly
Part of the lifestyle	Done for sport
Selecting healthy animals from herd	No selection of healthy animals
Leaving most of group / herd alive	Killing all of a group.
Letting the leaders pass	Killing the first animals through
Conservation education built into lifestyle	No awareness of conservation ethic
Selecting sex based on use/need	Killing indiscriminately
Taking only what was needed	Killing more than is needed
Sharing meat	Selling meat. Stories of dumptrucks coming from other communities to take caribou away.
Using all of the animal	Wasting meat
Taking elders along	Not practiced as much now
Asking permission to use the land	People coming from everywhere
Easy to track how many animals taken	Very difficult to track number of animals taken
Leaving the bones / remains to rest on the land	Carcasses at the dump or left on ice roads
Caribou weren't always accessible. Successful harvest depended on their migration route	Hunters access caribou wherever they are – regardless of migration pattern. Airplanes, roads, fast snowmachines, etc.
People lived with / followed caribou population cycles - harvest decreased when numbers were low	Even during low population cycles, harvest stays high because people can always access the animals.

Satellite collar locations of caribou from the Bluenose-East, Bathurst and Ahiak herds for 2005-2009 in winter are shown in Figure 5.22. These maps demonstrate the year-to-year variation in areas used by the three herds in winter, as well as the degree of overlap between neighboring herds. Overlap between neighbouring herds is common in winter. In 2005 Bathurst caribou (green) were scattered across a big area north of Great Slave Lake, with some overlap with Bluenose-East caribou (red). In 2006 the Bathurst collars were mostly east of Great Slave Lake and overlapped with Ahiak collars (purple). Tłı̨ch̓ hunters would have been hunting mostly Bluenose-East caribou.

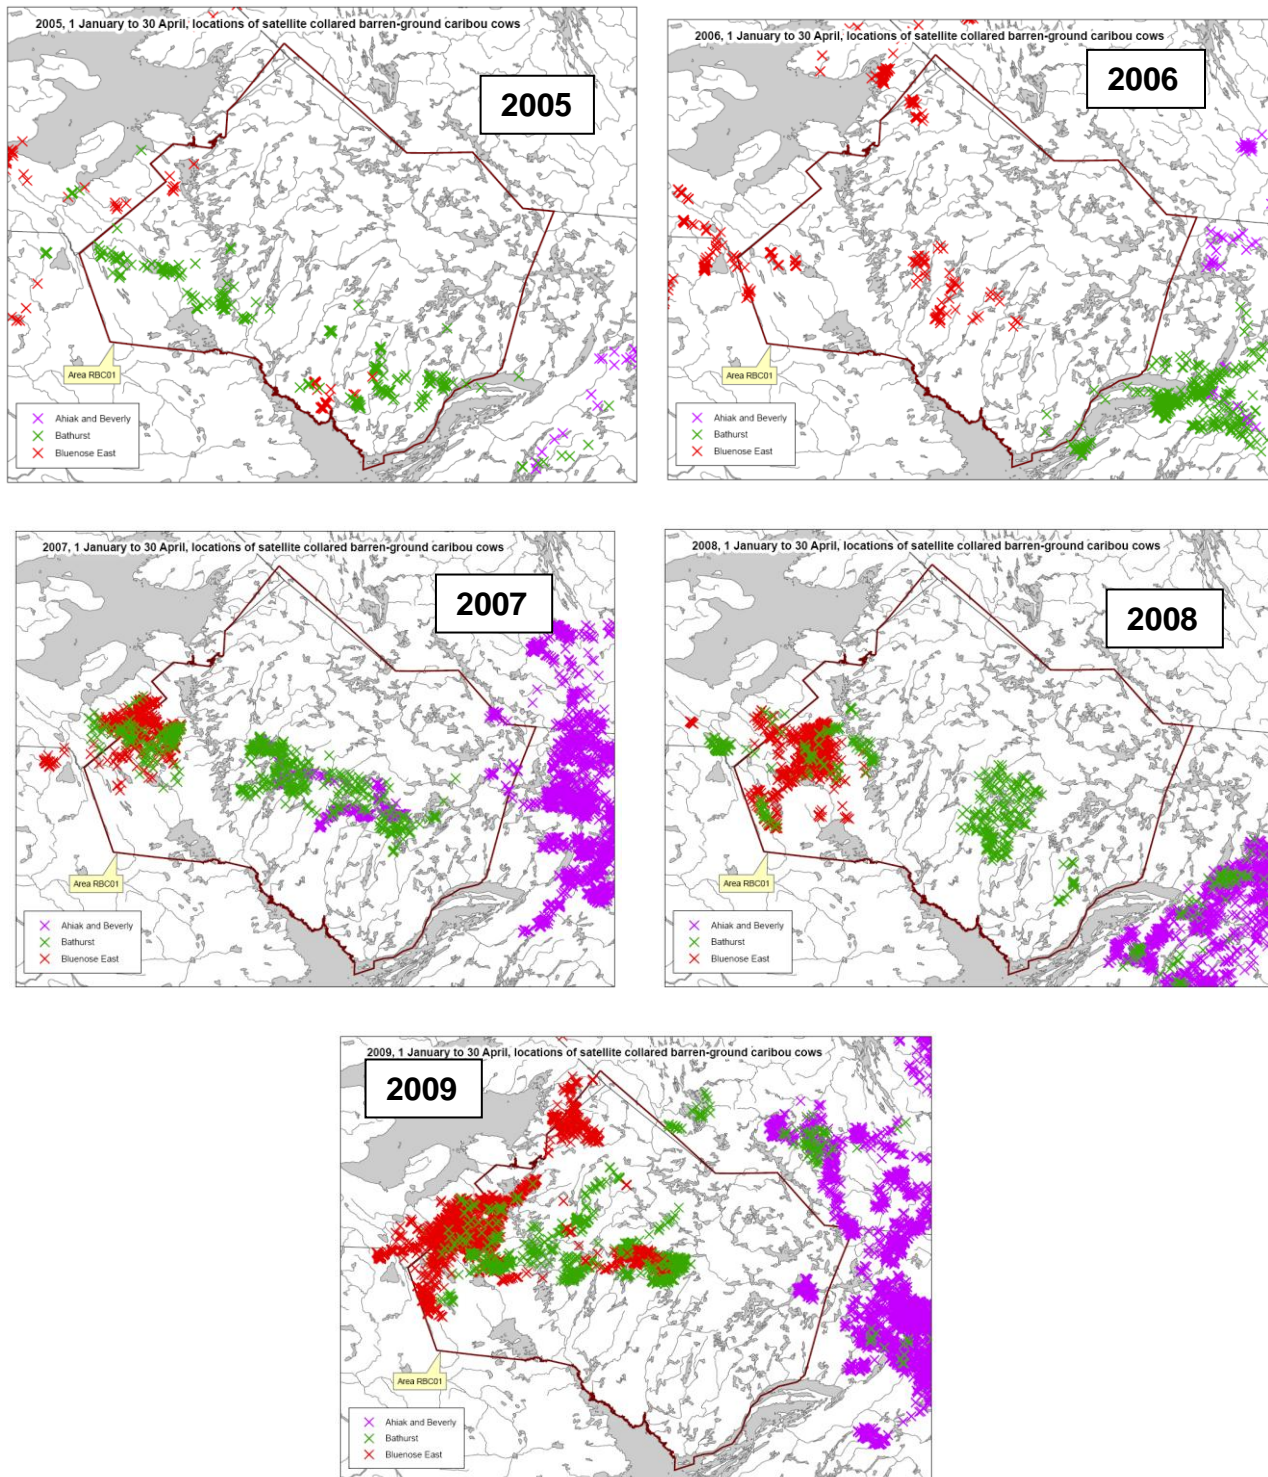

Figure 5.22. Satellite collar locations in winter of Bathurst, Bluenose-East and Ahlak caribou, 2005-2009.

In 2007 the Bathurst collars were back north of Great Slave Lake and overlapped extensively with Bluenose-East caribou south of Great Bear Lake. In 2008 the collar locations were generally similar to the previous year. In 2009 many caribou wintered north of tree-line in all three herds, possibly because of shallow snow on the tundra. Bathurst collars again overlapped extensively with Bluenose-East collars.

5.8.2 Resident harvest of Bathurst and other barren-ground caribou

The reported harvest of barren-ground caribou by resident hunters in the NWT is shown in Figure 5.23. Since 2006, NWT residents have been limited to bull-only hunting. Resident hunters from the Inuvialuit, Gwich'in and Sahtu Settlement Areas hunted primarily Cape Bathurst, Bluenose-West and Bluenose-East caribou. Resident harvest in these 3 land claim areas was reduced to 0 in 2006. Resident hunters from Yellowknife and the North/South Slave regions hunted primarily Bathurst caribou and possibly some Bluenose-East caribou in the fall and winter due to overlap on these ranges.

Figure 5.23. Reported annual resident harvest of barren-ground caribou in the NWT from 1983/1984 to 2007/2008. White bars are Yellowknife hunters, grey bars are hunters in Inuvialuit, Gwich'in and Sahtu Settlement Areas, and grey bars are North Slave (except Yellowknife) and South Slave regions. (From S. Carriere, ENR, Yellowknife)

Figure 5.24. Sex ratio (females: males) in barren-ground caribou taken by resident hunters in the North Slave region 1994-2008. (From S. Carriere, ENR, Yellowknife)

The largest numbers of barren-ground caribou taken by resident hunters were in the early 1990s. Over 2000 caribou were taken in 1992-1993 by residents. The resident harvest of caribou has declined since those years and by 2006-2007 and 2007-2008 was less than 200 caribou from all herds. Since 2006 only bull caribou can be taken by resident hunters, and the sex ratio (females to males) declined to 0 by 2007 (Figure 5.24).

5.8.3 Outfitter harvest of Bathurst caribou

The total harvest of caribou bulls by outfitters from 1997 to 2009 is listed in Table 5.13. The average annual harvest was 828 bulls, with the highest total in 2001 at 1,166 bulls, and declining harvest totals from 2005 to 2009. Maps of satellite collared Bathurst, Ahlak and Bluenose-East caribou indicate that the outfitter camps accessed mostly Bathurst caribou in most years in August and September, with some access to Bluenose-East caribou from the more western camps (Figure 5.25). The exception was in 2009 when most of the collared cows and bulls near outfitter camps were from the Bluenose-East herd. Collared Ahlak caribou were not near the outfitter camps in any year for which we have collar information.

Year	Numbers of tags issued	Number of bulls taken
1993	586	517
1994	485	309
1995	651	574
1996	770	684
1997	900	717
1998	959	784
1999	1118	943
2000	1147	960
2001	1342	1166
2002	1425	1150
2003	1252	910
2004	1163	912
2005	1211	850
2006	1241	730
2007	691	605
2008	610	419
2009	503	223

Table 5.13. Total number of caribou bulls taken by caribou outfitters in Wildlife Management Unit R, from records kept by North Slave ENR regional staff.

5.8.4 Total hunter harvest 2006-2009

With an average total of 415 bulls taken annually by outfitters (2006-2009), 100-200 caribou, primarily bulls, taken annually by resident hunters, and a “best guess” estimate of 4000-5000 cows and 1000-2000 bulls taken by aboriginal hunters, the total Bathurst harvest was likely in the range of 4000-5000 cows and 2000 bulls/year in the last 3 years. Harvest totals likely varied from year to year, depending on weather and accessibility of caribou from roads and communities.

Figure 5.25. Satellite collar locations of caribou from the Bluenose-East (red), Bathurst (green) and Ahlak (purple) herds in fall 2007 (above left), fall 2008 (above right), and in early September 2009 (bottom left). Camps used by outfitters are black triangles. Blue dots are satellite collared Bluenose-East bulls.

5.9 Wolves in the Bathurst range (DC)

Population sizes of wolves (*Canis lupus*) are difficult to estimate because wolves range over vast areas, exist at relatively low densities, have secretive behaviour, and limit their activity during daylight hours. Wolves that follow migratory barren-ground caribou add to the difficulty by having increased annual home range sizes. Wolf populations are composed of packs and lone individuals. Pack size usually varies seasonally while most lone wolves are only temporary situations (Mech and Boitani 2003). Consequently, counting wolves can be a complex and costly effort easily susceptible to biases and errors. Standardized, accurate, and cost-effective methods of assessing wolf distribution and abundance are lacking and need to be identified and implemented (Fuller et al. 2003).

What constitutes a wolf population can also be problematic. A wolf population can have a geographic, ecological or genetic basis (Fuller et al. 2003). Population assignment studies have not been done in the north although wolves are generally classified as boreal, tundra, or arctic wolves. Tundra wolves are also genetically distinct from wolves associated with prey resident in the boreal forest regions, therefore tundra and boreal forest wolves do not mix significantly during the breeding season (Musiani et al. 2007).

5.9.1 Wolf Den Site Monitoring

If trend (increasing, stable, decreasing) in the wolf population is sufficient for management then an index of wolf abundance can be used. An index of population size requires a measurable variable correlated with density (Caughley 1977). Tundra-denning wolves show a strong fidelity to a denning area and often return to the same site each year. Consequently, den site occupancy should be a suitable parameter for such an index. The assumption would be that with more wolves there would be more dens, ideally in a linear relationship. The treeless tundra and extended daylight hours allow wolves to be observed from the air which is usually not available in forested areas further south.

Wolves den throughout the range of the barren-ground caribou, especially on the tundra and tree-line areas where caribou can be expected during spring and summer. However, the distribution of wolf dens is not uniform and is influenced by habitat features and caribou movement patterns (Heard and Williams 1992). Wolves denning on the tundra tend to select areas on or near eskers and other similar landforms that resulted from melting glaciers (Mueller 1995, McLoughlin et al. 2004). The distribution of eskers on the tundra reflects the pattern of glacial retreat and was not uniform. Because wolves do incorporate esker distribution at the home range scale (McLoughlin et al. 2004), an index tracking wolf abundance must consider esker density in the survey design.

Wolves are territorial animals and normally defend an area as a pack (Mech and Boitani 2003). Wolves that hunt migratory barren-ground caribou do not appear territorial in winter but likely are in summer (Walton et al. 2001, Cluff et al. 2002, Frame et al. 2007). Therefore, an active wolf den at one site likely means that there is not another one nearby. From 1996 to 2006 surveys, the mean distance between the next closest active den was 13.0 km (SD = 5.5 km, n= 11 years) with a range of 5.5-23.8 km.

The wolf den survey area in the North Slave Region includes Aylmer and Clinton-Colden lakes to the east, the Nunavut boundary to the north, Point Lake and Jolly Lake to the west, and Lockhart and Fletcher lakes to the south (Figure 5.25). In 2009, the survey study area was divided into 744 grid cells encompassing over 74,400 km².

5.9.2 Den survey methods

Wolf den sites tended to be discovered opportunistically but in 1996, eskers on the central tundra of the Bathurst caribou range were systematically inventoried to locate dens. This inventory was part of a West Kitikmeot/Slave Study Society (WKSS) baseline study examining the relationship of wolves and esker habitat (Cluff et al. 2002, McLoughlin et al. 2004). The search effort also benefitted from revisiting den sites found previously (Williams 1990, Heard and Williams 1992, Mueller 1995). While most wolf dens are expected to be located on or near eskers, other survey opportunities have allowed other habitat types to be flown to test if wolves could have denned elsewhere. From 1997 to 2004, wolves were captured and radio-collared (Walton et al. 2001, Cluff et al. 2002, Frame et al. 2007) and their movements also confirmed the preponderance of eskers as denning locations. Since 1996, some eskers continued to be surveyed for dens but in an *ad hoc* manner while navigating between sites. However, in 2008, a 10 km x 10 km grid cell approach was formally adopted to better quantify den site occupancy. Sites of wolf dens surveyed in May-June 2009 are shown in Figure 5.26 and the numbers of active dens at that time are shown in Figure 5.27.

A wolf pup survey is also conducted in late summer to estimate recruitment. Ideally early fall is best when the pups travel with the adults. However, once wolves leave the den, they are not easily found without radio-collars. Therefore, den sites that were active in the June den survey are re-visited in early to mid-August to count pups. Because wolves can relocate their den, move to a rendezvous site, or an entire litter can fail, not all dens from the June survey remain active and the sample size for the August pup survey is invariably smaller than in the June survey. In 2009, a follow-up den survey was initiated in early July as a way to get an early count of pups and more precisely determine if early pup mortality or entire litter loss is occurring.

Figure 5.26. Wolf den survey in the summer/fall range of the Bathurst herd, May-June 2009. Blue line shows the flight path.

Figure 5.27. Number of active wolf dens on the Bathurst caribou summer range in early summer (May-June) 1996-2009.

Figure 5.28. Average wolf sightings per den on the Bathurst caribou summer range, 1996-2009.

5.9.3 Den survey results

Since 1996, 292 active wolf dens have been recorded for an average of 20.5 dens each year (SD = 3.5, range 14 to 28, $n = 14$ years, Figure 5.27). The search effort and geographical extent has varied over the years, complicating the trend analysis of wolf abundance if only dens are considered. However, a grid cell approach has been implemented as of 2009 and a retrospective analysis since 1996 is underway using flight tracks as a way to measure search effort and survey coverage. This will allow trend analysis of active den sites with variable survey effort among years as an index of wolf abundance.

In June 2009, only 40 wolves were sighted from the 25 active dens observed on the NWT tundra portion of the Bathurst range. Most dens had 1 or 2 wolves present while one den had 3 wolves, one had 4 wolves, and one had 5 wolves. When only one wolf is observed at the den, a second wolf is assumed. Therefore at an active den, the minimum number of wolves present would be the breeding pair (i.e., 2 wolves). The number of non-pup wolves (>1 year of age) observed at den sites has decreased since a peak during the late 1990s (Figure 5.28). For example in 2000, one den had 9 adults and 15 pups, the most ever recorded in the NWT. At that time, it was common to observe many wolves at a den site in June, however, now sightings typically consist of seeing only 1 or 2 wolves at a den.

The average number of pups has not shown much change over 14 years although the number of wolf dens active in June that remain active in August has plummeted (Figure 5.29). Although wolves can relocate their pups from dens to rendezvous sites, not many did so, at least far away from the den, in the late 1990s and early 2000s. Wolves now are either experiencing complete litter loss more often or are relocating pups to rendezvous sites much further away from the natal den. Since 2004, wolves are no longer radio-collared so we cannot locate the breeding pair to confirm if pups are still alive. However, the follow-up den survey we initiated in early July 2009 to count pups indicated only half of the dens were still active after a month. While some wolves may have moved their pups this early, pup mortality may also have increased. This would be consistent with the recent decline in caribou numbers.

Figure 5.29. Number of dens still active in August and average number of pups per den, in wolf dens surveyed in the Bathurst range, 1996-2009.

5.9.4 Detecting Change

If the number of active wolf dens corresponds linearly to wolf population fluctuations, then more active dens would mean more wolves. Similarly, few active dens would suggest a decline in the population. However, survey effort would have to be large to overcome local influences in wolf den activity. For example, if one or both members of a breeding pair are shot or trapped in the annual fur harvest, their den will not likely be active the following spring. Survey results must be robust to slight variations. However, if many wolves are harvested, then this mortality factor would likely be observed as reduced den occupancy over a greater area. Human-caused mortality is a significant factor for wolves and these tundra-denning wolves have been killed over 400 km from their den in the boreal forest during winter (Walton et al. 2001, Cluff et al., 2010). That harvest mortality of wolves can occur over long distances from where wolves den is an important consideration for wolf ecology and management. In recent years, wolf harvest has been low.

The number of adult wolves observed per den site will likely fluctuate with population size. Often yearlings and two-year-old wolves will remain at the den as associates and help raise their younger siblings. As the average number of adult wolves per den approaches 2.0 (e.g. Figure 5.28), population numbers are likely declining. Counts of pups may also provide supporting documentation of changes in wolf population numbers. Incidence of multiple breeding, whether from capture evidence or inferred, will also be useful to assess the abundance of food (prey) available.

5.9.5 Aerial surveys

Wolf abundance in late winter

In February/March 2006, a stratified random survey was conducted to estimate the number of caribou and wolves on the Bathurst caribou winter range (Mattson et al. 2009). That year, Bathurst caribou were wintering in the Artillery Lake and Lutsel K'e area. Survey cells were stratified as high or low caribou density over a total

area of 494,000 km² based on the distribution of satellite-collared caribou at that time. Those cells were further stratified by lichen occurrence and snow-water equivalence. Using those count data, 41,000 ± 8,430 caribou and 211 ± 66 wolves were estimated on the winter range study area (Mattson et al. 2009). Only 6 wolf-killed caribou were observed. The density estimates for both caribou and wolves were lower than expected and may have been influenced by having only 14 collared caribou available for the stratification technique. Also, that winter 104 wolves were harvested by a trapper from Fort Reliance.

Wolf sightings during aerial surveys for caribou

The Department annually conducts a number of aerial surveys to assess caribou composition and distribution. On many surveys, wolves are sighted. The Department recently examined if there are trends in wolf sightings and if relationships exist between number of wolves seen and survey search effort and number of caribou seen (Frame and Cluff 2009). However, infrequent surveys for some herds and inconsistent methodologies limited the analysis to only the North Slave area and from 1987 to 2008.

The number of wolves seen from year to year was variable with no clear patterns for either late winter or autumn surveys. Some years many wolves were observed, such as in 1991 or 2008, but then few wolves were observed the following year, and sightings increased the year after that. Interpreting such results is difficult by itself but becomes more uncertain when we consider that Bathurst caribou numbers were generally high and increasing from 1987 to 1995. It appears there was a weak pattern of wolf observations fluctuating from low to relatively high and back to low every few years, however because there are no estimates of wolf abundance for those years for comparison, we cannot state that those observations were representative of the wolf population and therefore do not necessarily represent trends in abundance. There was also no significant relationship between the number of wolves seen and the distance or time searched. This was not surprising because aerial caribou surveys also include areas where caribou are scarce or absent while they delineate current caribou winter range boundaries.

We also plotted flight track logs, caribou and wolf observations from late winter and fall caribou composition surveys for the Bathurst caribou herd for 2006, 2007, and 2008. We buffered these flight paths by 400 meters on each side to reflect the standard range of view by observers in these surveys. We analyzed these locations based on several ecological features and did the same for five random points for each wolf location to look at sightability patterns of wolves from the air. The ecological features we examined were habitat type, cover classification, distance from wolf sighting to a lake, distance from the wolf sighting to caribou, and the local caribou abundance. Some of these features are interrelated and we looked for these patterns in our development of a sightability model.

We use Akaike's Information Criterion, adjusted for small samples sizes (AIC_c) to test nine models (Frame and Cluff 2009). The best fitting model included proximity to lake, proximity to caribou, and local caribou abundance. Neither proximity of the wolf sighting to lakes or local caribou abundance on their own contained any useful information differentiating wolf observations from random points. Proximity to caribou influenced all the models even when tested alone (Frame and Cluff 2009). Not surprisingly, wolves selected for areas where there are caribou, especially where caribou were abundant, and were more readily seen in open areas such as lakes than elsewhere.

5.9.7 Conclusions

Overall, our data on wolf dens and wolves indicate that abundance and productivity have in the last 5 years fallen rapidly. Annual wolf den site occupancy is likely a reasonable index of population size, and therefore can be considered a measurable variable correlated with density (Caughley 1977). Indices are useful to draw comparative inferences about populations at different times and/or locations. However, because the exact relationship between an index and true population size is usually not known, there is typically uncertainty about the validity of the comparisons made (Lancia et al. 2005). However, efforts to locate all active dens within a given area may offer a coarse estimate of population size.

Aerial surveys for wolf abundance would be feasible if they occurred in late winter and stratified by caribou abundance, specifically immediately after a compositional survey for caribou. A grid-based survey stratified by this detailed level of caribou abundance would have the best chance of seeing wolves in all habitats and thus reduce the influence of sightability factors. However, because of the difficulty sighting wolves in forested areas, aerial surveys that do not include a measure of detection probability would be flawed. Typically, a detection rate would be needed using radio-collared wolves present during the survey and this detection rate applied to the population estimate from the stratified random survey for a more unbiased estimate of wolf numbers. Because such a survey would estimate wolf and caribou density, a predator/prey ratio could be calculated which would also provide a meaningful measure of wolf abundance.

5.10 Mining and other development (JB & JA)

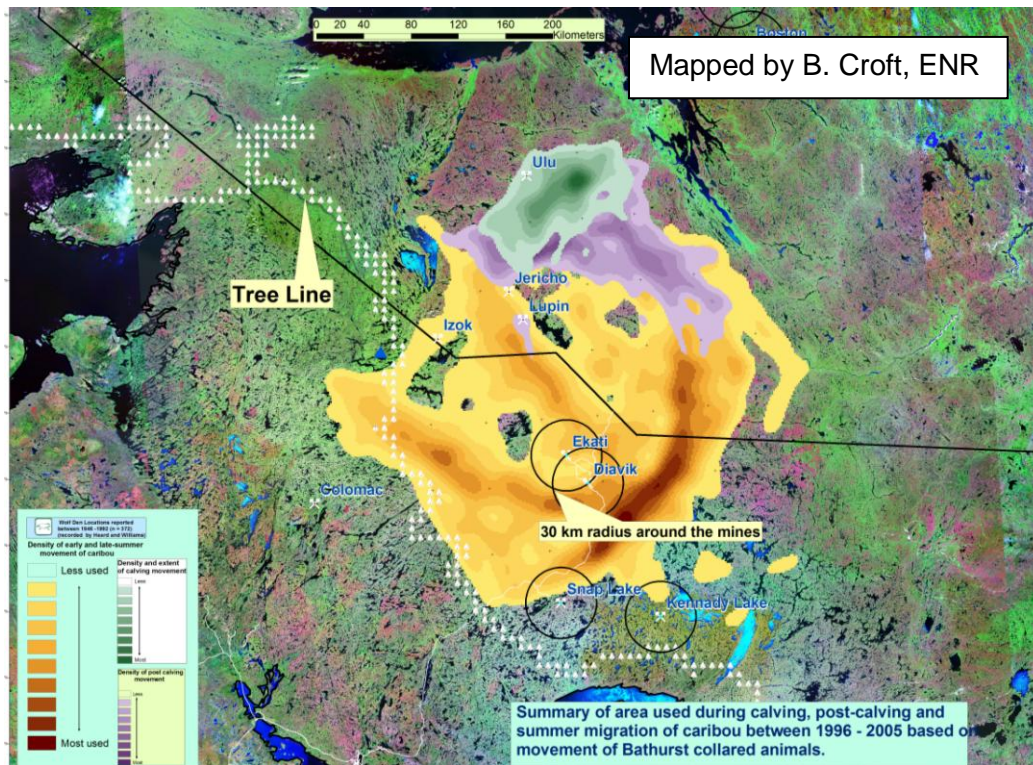

Figure 5.30. Calving and summer ranges of the Bathurst caribou herd, 1996-2005, with 30 km radius around the active mines. The map shows the calving (green), post-calving (purple) and summer (yellow) ranges of the Bathurst herd, based on satellite collar caribou locations from 1996 to 2005. Darker areas had greater use by caribou. The Ekati and Diavik diamond mines are in the summer range and the Snap Lake mine is on the edge of the summer range.

The cumulative effects of active mines and associated roads and traffic on the Bathurst caribou herd have been studied by biologists and by staff and consultants at the mines from the early 2000s to the present day (2009; Figure 5.30). We include here a summary of a draft report by J. Boulanger and co-authors in 2009 on a Zone Of Influence (ZOI) around the diamond mines. In addition, ENR has had a demonstration project underway that uses a combination of modeling approaches to assess effects of the diamond mines on the Bathurst herd on its summer range. The project has not been written up fully but we include a brief summary on initial trends.

A study by Johnson et al. (2005) first reported avoidance of the active diamond mines in the Bathurst summer range, based on spatial analysis of the summer habitat and satellite collar locations. Since then, further analyses by consultants to the mines (Golder 2008 a&b) and Boulanger et al. (2009) have evaluated

use by caribou of areas within 30 km of the mines using satellite collar data and data from systematic aerial surveys of caribou by mine staff.

Boulanger et al. (2009) used data from aerial surveys and locations of satellite collared cow caribou as inputs to a model to account for patterns in habitat selection. They then constrained the zone of influence curve to asymptote, such that the average distance from the mine complex where caribou habitat selection was not affected by the mine could be estimated. Around the Ekati-Diavik mine complex during the operation period for both mines they detected a 14 (CI=12-15.5) km zone of influence from the aerial survey data, and a weaker 11 (CI=1-17) km zone from the satellite-collar locations. From the aerial survey data it was estimated that caribou were 4.18 (CI=3.6-4.9) more likely to select habitat at greater distances from the mine complex than within the zone of influence.

Boulanger et al. (2009) also used data from the CALPUFF (Rescan 2006) dust deposition model to explore if zone of influence was associated with dust or total suspended particles (TSP) deposition. The CALPUFF model generates isopleths of dust deposition, which predicted that TSP declines rapidly >2 km from mine development and were indistinguishable from background deposition rates at a distance of 14–20 km from the Ekati-Diavik mine complex (Rescan 2006). Results of analyses suggested that TSP was a significant predictor of caribou occurrence, and furthermore suggested that caribou would avoid areas with even low levels of TSP which can occur up to 14-20 km from mine areas. These results should be interpreted cautiously given that this was a study of association rather than a controlled study. For example, it was likely that other anthropogenic factors beyond TSP influenced caribou distribution in the immediate proximity of mine areas. Low-frequency noise from heavy machinery and blasting could contribute to avoidance by caribou.

Boulanger et al. (2009) estimated that the area of reduced caribou occurrence from the Ekati-Diavik mine complex is ~6.7% of the 33,000 km² core and ~4.2% of the high use area of summer range of the Bathurst herd. Cumulative impacts from other sources of disturbance on the landscape (Johnson et al. 2005) could have wider implications to the ecology and health of the herd. Boulanger et al. (2009) were unable to estimate the proportion of the herd that is affected by development, and thus the population-scale costs are unknown (Wolfe et al. 2000). However, these results depict clear separation of the effects of development from natural variation in habitat use.

Further analyses by C. Johnson (pers. comm.) and Daniel et al. (2009) added further perspective on the effects of the diamond mines on the Bathurst herd. Spatial analysis by C. Johnson indicates that the habitat within the ZOI is not unique and that the 96% of the summer range not within the ZOI has an abundance of the habitat types within the ZOI. In addition, Daniel et al. (2009) used an energetics model developed for Porcupine caribou by Russell et al. (2005) to assess whether caribou that came within close range of the mines might be adversely affected by feeding less or expending more energy on running or walking. The analysis thus far suggests that these effects have been limited, in large part because caribou avoid the mines, as described earlier, and a relatively small proportion of the herd comes near the mines. Further, caribou are most likely to come into the mines' proximity during spring and fall migration, when they tend to maintain strong directional movement, thus further limiting their potential exposure to noise or traffic that might affect their behavior.

Overall, the studies to date of the effects of the diamond mines on the Bathurst herd show a clear avoidance of the active mines to a distance of 14 km or possibly at longer distances, but this affects only a small proportion of the herd's current summer range. Behavioural effects on caribou feeding or energetics have been limited, in large part because caribou avoid the mines and are on the move when they are most likely to be near the mines. Although the disturbance effects of the mines on the Bathurst caribou herd appear thus far to be limited, they should not be trivialized: human infrastructure can at some scale of intensity lead caribou or reindeer to abandon an area altogether (Nellemann et al. 2003, Cameron et al. 2005). The greatest effect of the mines in recent years has been increased road access for hunters.

5.11 Declines in other NWT/NU herds (JA)

Three NWT barren-ground caribou herds experienced similar patterns in decline in recent years: the Cape Bathurst, Bluenose-West and Bathurst herds all declined relatively slowly, then declined at an accelerated rate at lower herd size (Figure 5.31).

The Cape Bathurst herd declined at about 4% per year from 1992 to 2000, then at a rate of 14% per year from 2000 to 2006. The Bluenose-West herd similarly declined by about 4% per year from 1992 to 2000, then at a faster 13% per year from 2000 to 2006. The Bathurst herd declined at about 5% per year from 1996 to 2006, then by 22-23% per year from 2006 to 2009.

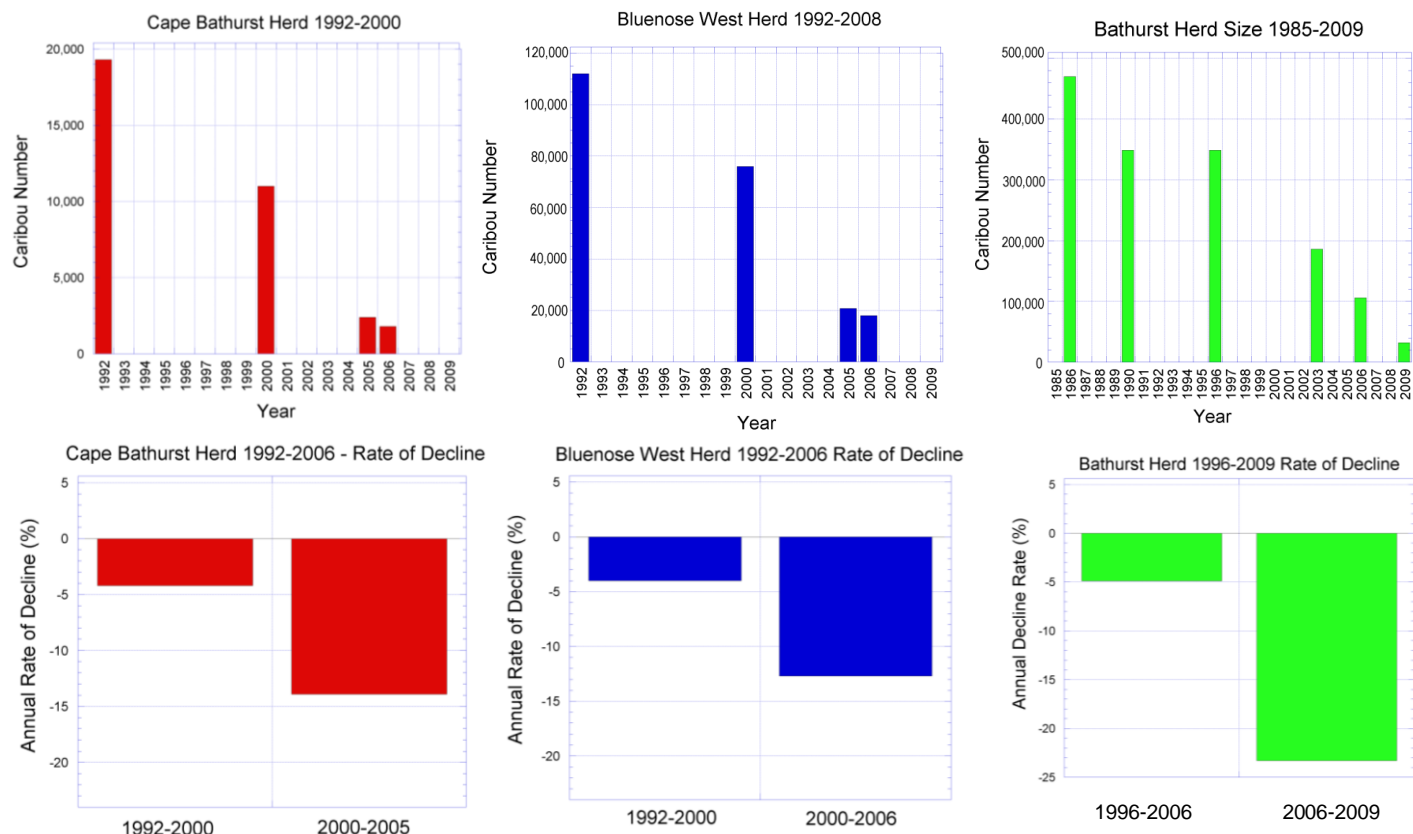

Figure 5.31. Comparison of declines in estimated population size and annual rate of decline in the Cape Bathurst, Bluenose-West and Bathurst herds in the 1990s and 2000s.

Trends in the three herds are considered in greater detail on the following pages.

5.11.1. Decline and harvest management in the Cape Bathurst herd

Figure 5.32. Rate of decline (top left), harvest as a % of herd size (bottom left), estimated 2005 harvest, and population trend indices for the Cape Bathurst herd 2000-2006 (top right).

Figure 5.33. Stable trend in the Cape Bathurst herd 2006-2009. All harvest was closed on this herd in 2007.

In the early 2000s, late calving and low calf:cow ratios were recorded on the calving grounds of the Cape Bathurst herd (J. Nagy, ENR, unpublished data; Figure 5.33). These observations would indicate that the caribou were nutritionally limited, and likely would have been declining naturally without hunting. The estimated hunter harvest for the Cape Bathurst herd was around 730 caribou in 2005 (primarily cows; J. Nagy

unpublished data). If this harvest was about the same in earlier years, then 730 caribou would be about 3% of the herd in 1992, about 7% in 2000, and about 30% in 2005. This harvest would have accelerated the herd's downward trend from natural factors. By recommendation of the Wildlife Management Advisory Council (NWT) (WMAC-NWT) and implemented by ENR, all harvest on this herd was closed in 2007. A July 2009 survey of this herd indicates a stable trend from 2006 to 2009 (Figure 5.33). This result suggests that the harvest contributed significantly to the herd's earlier decline, particularly at low numbers.

5.11.2. Decline and harvest management in the Bluenose-West herd

Figure 5.34. Rate of decline (top left), harvest as a % of herd size (bottom left), estimated 2005 harvest, and population trend indices for the Bluenose-West herd 2000-2006 (top right).

Figure 5.35. Stable trend in the Bluenose-West herd 2006-2009. Harvest was reduced to 4%, mostly bulls, in 2007.

Patterns of decline in the Bluenose-West herd in the early 2000s were similar to those in the Cape Bathurst herd. Late calving and low calf:cow ratios on the calving ground indicate that the caribou were nutritionally

limited, and likely would have been declining naturally without hunting (J. Nagy, ENR, unpublished data; Figure 5.34). The estimated hunter harvest for the Bluenose-West herd was around 1900 caribou in 2005 (primarily cows; J. Nagy unpublished data). If this harvest was about the same in earlier years, then this harvest would be about 2% of the herd in 1992, about 3% in 2000, and about 9% in 2005. Evaluation of the decline by C. Nicolson suggests that the harvest may have been higher than 1900/year in the 2000s, assuming that natural mortality rates of cows were at the lower end of the range reported elsewhere. By recommendation of WMAC-NWT and the Gwich'in and Sahtu Renewable Resource Boards, a Total Allowable Harvest was set at 720 caribou (4% of the herd), with at least 80% bulls in 2006-2007. A July 2009 survey of this herd indicates a stable trend from 2006 to 2009 (Figure 5.35). As with the Cape Bathurst herd, this change suggests that the harvest had contributed significantly to the decline in the early 2000s, especially at low numbers. The Bluenose-West and Cape Bathurst herds were in 2009 the only barren-ground herds monitored by GNWT with a stable trend.

5.11.3 Decline and harvest in the Bathurst herd

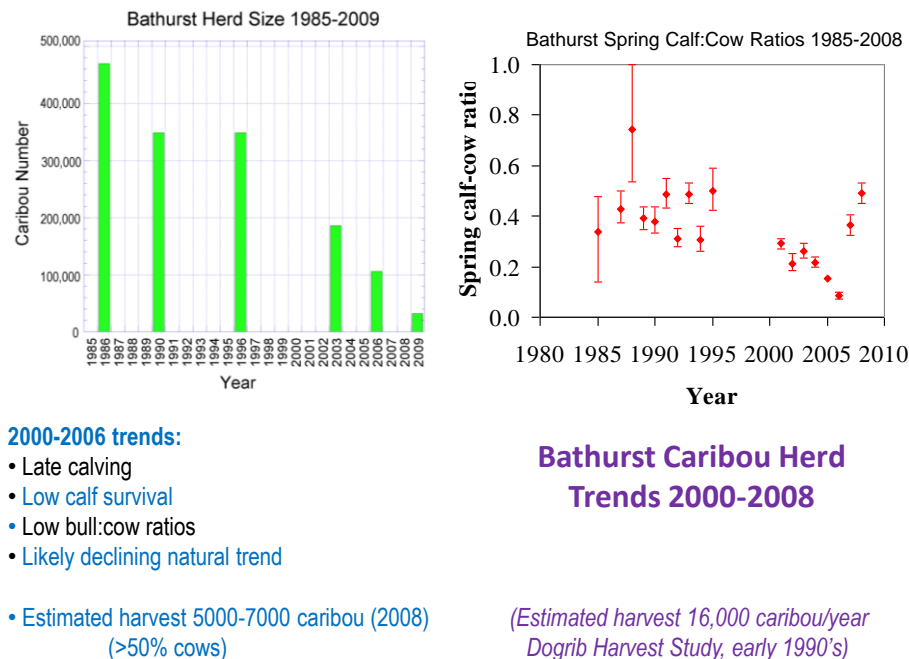

Figure 5.36. Herd size (top left), spring calf:cow ratios (top right), population trend indices, and estimated hunter harvest (bottom) in the Bathurst caribou herd, 1985-2008.

An evaluation of the decline of the Bathurst herd shows similarities to the declines of the Cape Bathurst and Bluenose-West herds. Between 1996 and 2006 the herd declined at an average rate of 5% per year (Figure 5.36). Spring calf:cow ratios in the early 2000s were low, indicating that the herd was most likely nutritionally limited and would have declined naturally, without hunting, over this period. After 2006 the herd declined at a staggering 22-23% per year.

The hunter harvest has not been well documented for the Bathurst herd, but an estimate of 7000 caribou/year (5000 cows, 2000 bulls) is probably realistic (see Section 5.7; Figure 5.37). These totals are well below the 16,000/year for this herd estimated by the Dogrib Harvest Study in the early 1990s. As with the other two herds, this harvest would have been barely 2% of the herd in 1996, increasing to 4% in 2003, 7% in 2006, and 22% in 2009. A lower harvest of 3000 caribou produces a similar result, with 15.6% of the herd taken in 2009.

The Bathurst herd has been hunted by more communities in the NWT than any other. With winter roads to the communities and diamond mines, access by truck and skidoo has increased and the caribou have been accessible even at very low numbers.

Figure 5.37. Rate of decline (% of herd lost per year) in the Bathurst herd 1996-2006 and 2006-2009 (left), and harvest of 7000 caribou per year as % of herd in 1996, 2003, 2006 & 2009 (right).

6.0 Bathurst herd decline: modeling outcomes using OLS models (JB)

Boulanger et al. (2009) used a data-driven demographic model to explore potential causes of the Bathurst decline. This approach used all the direct data (e.g. estimates of breeding cow numbers) and indirect data (calf-cow ratios, bull/cow sex ratios, measures of fecundity from the breeding ground) to estimate demographic parameters as well as test biological hypotheses regarding causes of the Bathurst decline.

It is beyond the scope of this report to provide all the details of the model methodology and we suggest readers interested in these details should consult Boulanger et al. (2009). We will, however, provide a synopsis of how this method was applied and the main outcomes of the modeling effort.

The main challenge with fitting demographic models to the Bathurst caribou herd, and, indeed, to most barren-ground caribou herds in Canada, is the lack of direct estimates for demographic parameters. For example, although direct estimates of survival for adult females were available from satellite collars, sample size was low. Most information on the demographics of the Bathurst herd came from indirect sources such as composition counts in June (calving), late October (fall rut) and March or April (late winter) that produce calf:cow and bull:cow ratios.

To deal with the lack of direct demographic rate estimates we adopted a model that considers multiple data sources developed for deer and elk by White and Lubow (2002). The main distinction and advantage of this approach is that both direct and indirect sources of demographic information are used to produce model-based estimates of demographic parameters, thus relaxing the need for direct (individual satellite collared-based) estimates. In addition, this approach allows the evaluation of multiple hypotheses regarding temporal variation and trends in herd demographic parameters (White and Lubow 2002, Phillips and White 2003) using information theoretic methods of model evaluation (Burnham and Anderson 1998).

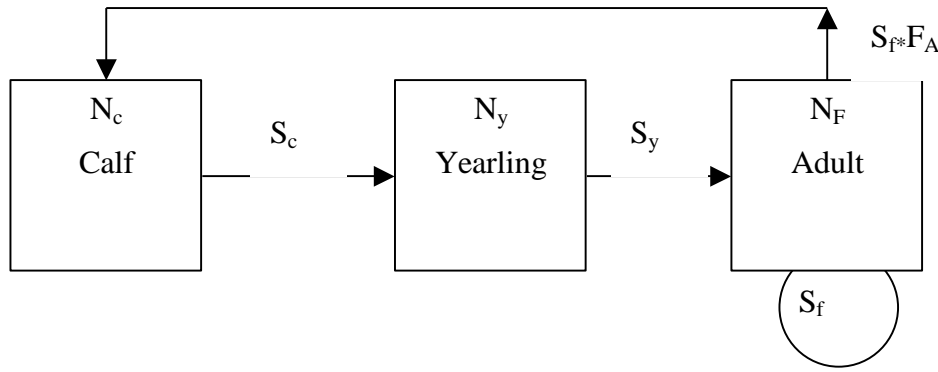

Figure 6.1: Underlying stage matrix life history diagram for the caribou demographic model. This diagram pertains to the female segment of the population. Nodes are population sizes of calves (N_c), yearlings (N_y), and adult females (N_F). Each node is connected by survival rates of calves (S_c), yearlings (S_y) and adult females (S_f). Adult females reproduce dependent on fecundity (F_A) and whether a pregnant female survives to produce a calf (S_f). The male life history diagram was similar with no reproductive nodes.

The basic demographic modelling exercise had the following steps. First a base demographic model was formulated which divided caribou into three separate cohorts as described in Figure 6.1. This model was based upon the population of caribou that calve on the Bathurst calving ground each year. It was assumed that there was no net movement of caribou to other calving grounds (as tested with multi-strata models in Section 4.0). We only had direct estimates of adult survival and population size of adults. However, information regarding fecundity (the proportion of females giving birth) could be estimated from calving ground composition surveys. Calf-cow ratios contained information about calf survival, fecundity, and adult survival since all these components related to the number of cows and calves observed on the calving ground. Therefore, it was possible to also mathematically formulate and model data from composition surveys to further inform the demographic model.

The demographic model generated predictions of population size, demographic parameter values (i.e. survival, fecundity) as well as prediction of corresponding field measurements (i.e. calf-cow ratios). Therefore, it was possible to supply a set of initial values of population size, survival rates, and fecundity rates and then assess how close model predictions were to those observed in the field. We formally assessed the difference between field measurement and model predictions using a penalty term.

$$Penalty = \left[\frac{(Model\ prediction - Field\ observation)}{SE\ of\ Field\ observation} \right]^2$$

The penalty term expressed the difference between model predictions and field observations in units of standard error of the field measurements. This accomplished two objectives. First, it standardized the difference between field measurements (i.e. population size, calf-cow ratios, survival rates) into standard error units therefore allowing easy comparison of estimates even though the original units of measurement were different. Second, it considered the level of precision of field measurement so that differences between model and field estimates based upon precise (low standard error) units of measurement would receive a higher penalty term than comparisons based upon imprecise (high standard error) measurements. For any run of the model it was then possible to add up all the penalty terms from each of the field and model comparisons to arrive at a total penalty score which indexed the overall fit of the model to the field data.

Using the penalty-term approach, we were able to propose a set of assumptions about demography and test how well the resulting predictions from the model fit the data as indexed by the penalty terms. The next step was then estimating the most likely parameter values given the set of underlying assumptions about demography. For example, we might test a model that assumed that adult survival, fecundity, and calf survival were all constant from 1985 to 2009. We had estimates of adult survival from 1996 to 2009 from

collars but not for other years and therefore some parameters had to be estimated based upon the underlying demographic model used. To accomplish this we used an optimization algorithm. This computer algorithm basically iteratively varied all the parameters within the model within the constraints set by the underlying assumptions (i.e. all parameters constant from 1985-2009) so that the resulting penalty term from the model was minimized. By doing this it estimated the most likely set of parameter values based upon the set of assumptions proposed about caribou demography. We then used this approach to propose a set of assumptions about caribou demography, for example, all parameters did not vary, or only survival declined linearly through time, and estimate *the most likely parameter values based upon these assumptions*, as well as assess the model fit based on penalty terms.

Our main objective with the demographic model exercise was to formulate the simplest demographic model that adequately explained the observed trends in Bathurst caribou demography. In general, a model that has a large set of assumptions (and parameters) may exhibit lower penalty terms and therefore “fit” the data better than a simpler model. For example, a model that estimated a model parameter for every field measurement would have a penalty term of 0 but this model would not tell us anything about overall demographic trends. The best model therefore balanced the complexity, or the number of assumptions about demography (as reflected in the number of estimated terms or parameters), with the fit of the model to the data as partially dictated by the sample size of field measurements available.

This topic has been theoretically formalized by the Akaike Information Criterion or AICc score. Briefly, the AICc score considers the fit of a model (as indicated by the penalty term) and model complexity (as indicated by the number of parameters). A lower AICc score suggests the most parsimonious model which balances bias (model fit) and precision (model complexity) (Burnham and Anderson 1998). The basic formula for the Akaike Information criterion is the sum of penalties plus 2 times the number of model parameters. So, the AIC score further penalizes the penalty score by two times the number of parameters. The difference in AICc values between the most supported model and other models (ΔAICc) was also used to evaluate the fit of models when their AICc scores were close. In general, any model with a ΔAICc score of less than 2 was worth considering. In addition, the proportional support of each model, or AICc weight (w_i) was considered in evaluating the support of each model. The AIC weights, or “weight of evidence” add up to 1 for all models considered. All parameter estimates were model-averaged using AICc weights to account for model selection uncertainty.

6.1 Model outcomes for the Bathurst herd

We proposed a suite of models that considered variation in calf survival, fecundity, and adult female survival. Male survival was held constant for all models due to the lack of field measurements pertaining to the male segment of the population. Variation in adult female survival was modelled using polynomial regression terms and “broken stick” models, however, for the sake of brevity we provide a verbal description of models in Table 3 and encourage readers to consult Boulanger et al. (2009) for more details. In short, models in which adult survival declined were most supported by the data as indicated by lower penalty terms as well as lower AICc scores. This result suggests that based upon all of the field measurements available, the decline of the Bathurst herd was associated with a directional decline in adult female survival coupled with declines in calf survival and fecundity. The hypothesis that the decline was due to just variation in productivity and a constant survival rate was less supported (Model 3) by the available field data (Boulanger et al. 2009).

Table 6.1: A synopsis of AICc model selection results from OLS deterministic caribou model as further detailed in Boulanger et al. (2009). Sample-size adjusted Akaike Information Criteria (AICc), difference in AICc between most supported and given model ($\Delta AICc$), Akaike weight (w_i), the number of parameters (K), effective sample size (ESS), and sum of penalties (ΣPen) are displayed. Effective sample size (the number of model and field estimate comparisons used to estimate ΣPen) was 56 for all models. Trends were not modelled in yearling and adult male survival due to lack of corresponding field data for these parameters.

No.	Model	AICc	$\Delta AICc$	w_i	K	ΣPen
1	➤ Adult female survival declined linearly from 1985-2009 ➤ Productivity (calf survival/fecundity) declined until a lowpoint in 2005, rebounded in 2006, then declined.	391.32	0.00	0.46	15	349.3
2	➤ Same as model 1 except adult female survival declined steeply after 2007	391.44	0.12	0.40	16	345.5
3	➤ Same as model 1 but adult female survival was constant (did not decline)	401.46	10.14	0.00	14	363.2
4	➤ All parameters were constant	1371.78	980.46	0.00	8	1352.7

The best way to consider these results is through model-averaged parameter estimates (Figures 6.2 and 6.3). Model averaged parameters are estimates based upon all models in the analysis with weight given to models that were most supported by the field data. It can be seen that adult female survival rates declined steadily until 2007 after which the decline was accelerated. Calf survival was relatively constant until 1995 after which it declined until a rebound after 2006 followed by a decline. Fecundity declined to a low point in 2005, then increased and then remained constant. Productivity (the product of fecundity measured on the calving ground times calf survival) suggested that productivity declined in unison with calf survival, rebounded in 2006 and then declined.

Figure 6.2. Trends in model-averaged estimates of parameter values from models in Table 6.1. Productivity as estimated by fecundity times calf survival is given for reference. Adult male survival (S_m) was 0.64 and yearling survival (S_y) was 0.86 for all years because temporal trends were not simulated in these parameters..

Figure 6.3 Model averaged OLS demographic model estimates compared to field estimates for late winter calf survival data and adult survival data. Field estimates have associated 95% confidence intervals.

The model fit all field data reasonably well with model-averaged predictions overlapping confidence intervals from field measurements in most cases (Figures 6.3 and 6.4). Calf-cow ratios that were adjusted for declining adult survival suggested that field calf-cow ratios overestimated productivity between 2007 and 2009. Model predictions were extrapolations of actual field trends for some relationships such as bull/cow ratio and adult survival, as those parameters were not measured in the 1980s or early 1990s. The adult female survival estimate was within the confidence intervals of point estimates of adult female survival from satellite collar based estimates. However, the precision of these estimates was low (as indexed by large confidence intervals) and estimates are only available after 1996. Therefore the model-based estimate is still within the realm of possible field measurements. Model averaged population estimates suggest declines in all cohorts (Figure 5).

It was also possible to reconstruct the current age structure of the Bathurst herd by expanding the base demographic model to track the fates of successive age cohorts. These results suggested that the current age structure of caribou is dominated by younger caribou and older caribou (See Figure 5.20, section 5) due to low recruitment up to 2005 followed by a brief surge in recruitment in 2006-2007.

Figure 6.4. Model-averaged OLS demographic model estimates compared to field estimates for fall survey data. Field estimates have associated confidence intervals.

Figure 6.5: Model-averaged population estimates from OLS deterministic models.

6.2 Assessment of the impact of harvest on trends in adult survival

OLS model estimates suggested that adult cow survival declined from 0.86 in 1985 to 0.76 in 2006 followed by an accelerated decline down to 0.67 in 2009 for a net change of 19 % (Figure 6.6). One potential factor for this decline could be a relatively constant harvest on the population as it declined. Accurate estimates of recent caribou harvest are unavailable, although a minimum annual estimate based on interviews and check stations is in the likely range of 3000-5000 adult cows/year. The Dogrib Harvest Study (1988-93) for the Bathurst caribou herd assessed mean harvest at 8380 (range: 3318-13107) cows and 7484 (range: 3855-10073) bulls per year (Table 6.2).

Table 6.2: Estimates of harvest from Dogrib Harvest Study. Population estimates are based upon model-averaged OLS estimates. The percentage harvest is simply the number harvested divided by the population estimate for bulls and cows respectively. Estimates from the Dogrib Study do not include potential wounding loss. Percentages are based upon population levels from 1988-1993 and are most likely higher with current population levels.

Year	OLS model estimate ¹		Caribou harvested		Proportion of \hat{N}	
	\hat{N} bulls	\hat{N} cows	bulls	cows	bulls	cows
1988	105866	234567	4606	3318	4.35%	1.41%
1989	101303	230563	3855	4730	3.81%	2.05%
1990	97736	225611	8970	8450	9.18%	3.75%
1991	94728	219798	10073	11626	10.63%	5.29%
1992	92023	213238	9685	9046	10.52%	4.24%
1993	89301	205878	7712	13107	8.64%	6.37%
Average			7484	8380	8.56%	4.34%

¹Model-averaged estimates from models in Table 6.1

We contrasted the change in mortality that was estimated as 1-the OLS model averaged survival rate (Figure 6.3) with proportional harvest mortality for adult cows as estimated by harvest levels divided by OLS population size estimates. From this it can be seen that harvest had relatively little impact on the population until 2000 after which the proportional mortality increased. Harvest rates of 3000, 5000, and 8000 resulted in proportional mortality of 11.6%, 19.3% and 30.9% of the population at 2009 population size. The slope of the proportional harvest curves was roughly parallel to the accelerated mortality curve after 2007, suggesting similar rates of change in mortality could be induced by a constant harvest rate at lower population sizes. The shapes of the curves at harvest rates of 3000, 5000, and 8000 cows are similar; actual harvest year to year most likely varies, but a non-declining harvest would in all cases mean that an increasingly large proportion of cow mortality was due to the harvest.

Under the assumption of minimal harvest pressure on the herd in 1985, the cow mortality estimate for this period (14%) could be conceptualized as natural cow mortality (i.e. mortality from predation and other natural causes). By 2009 cow mortality increased to 0.33, a net change of 19%. Comparing this net change to harvest proportion suggests that an average harvest level near 5000 cows could cause the same net change in mortality as estimated by the OLS model. Because harvest levels are uncertain and the effects of predation are unknown, conclusions about the role of harvest in the accelerated Bathurst decline 2006-2009 must be made with caution.

Multi strata models (Section 4) suggest a slight but not statistically significant increase in emigration rates from the Bathurst which would also cause survival to decrease given that emigration would appear similar to mortality. However, the low and statistically insignificant levels of net movement, and observed declines in the Ahiak and Bluenose-East herd from 2006-9 suggests that that it is extremely unlikely that movement to other herds could cause the observed trends in mortality.

Figure 6.6: Trends in proportion of adult cows harvested annually as a function of model-averaged OLS estimates of adult cow population size, corresponding calving ground survey adult cow estimates, and hypothetical harvest levels of 3000, 5000 and 8000 cows. Model-averaged estimates of mortality rate (1- survival rate) for adult cows are also shown for reference.

7.0 Looking ahead: prospects for the Bathurst herd (CN & JB)

We used a simple deterministic model, the Caribou Calculator devised for the Porcupine herd and adapted by C. Nicolson to the Bathurst herd, to look ahead for a period of 5 years under various sets of conditions. These model projections are shown in Figures 7.1 and 7.2.

We also used stochastic simulations based on OLS model values to consider the Bathurst herd's likely future depending on cow and calf survival rates. We incorporated variance in model parameters as survival rates, weather and other variables in the real world are never fixed. Given the herd's current rapid decline rate and the prospect of changes to harvest, projections for more than 5 years would have little value.

7.1 Bathurst Caribou Calculator Simulations

The graphs on this page were generated from the Bathurst Caribou Calculator. They are not predictions, but they give some idea of likely trends under various sets of conditions.

If current conditions continue, the herd may disappear in 4-5 years or drop to very low numbers. Under optimal conditions and no harvest, the herd may stabilize and begin a modest increase. With no cow harvest, little or no bull harvest and good environmental conditions, the herd should either stabilize or decline more slowly than in recent years.

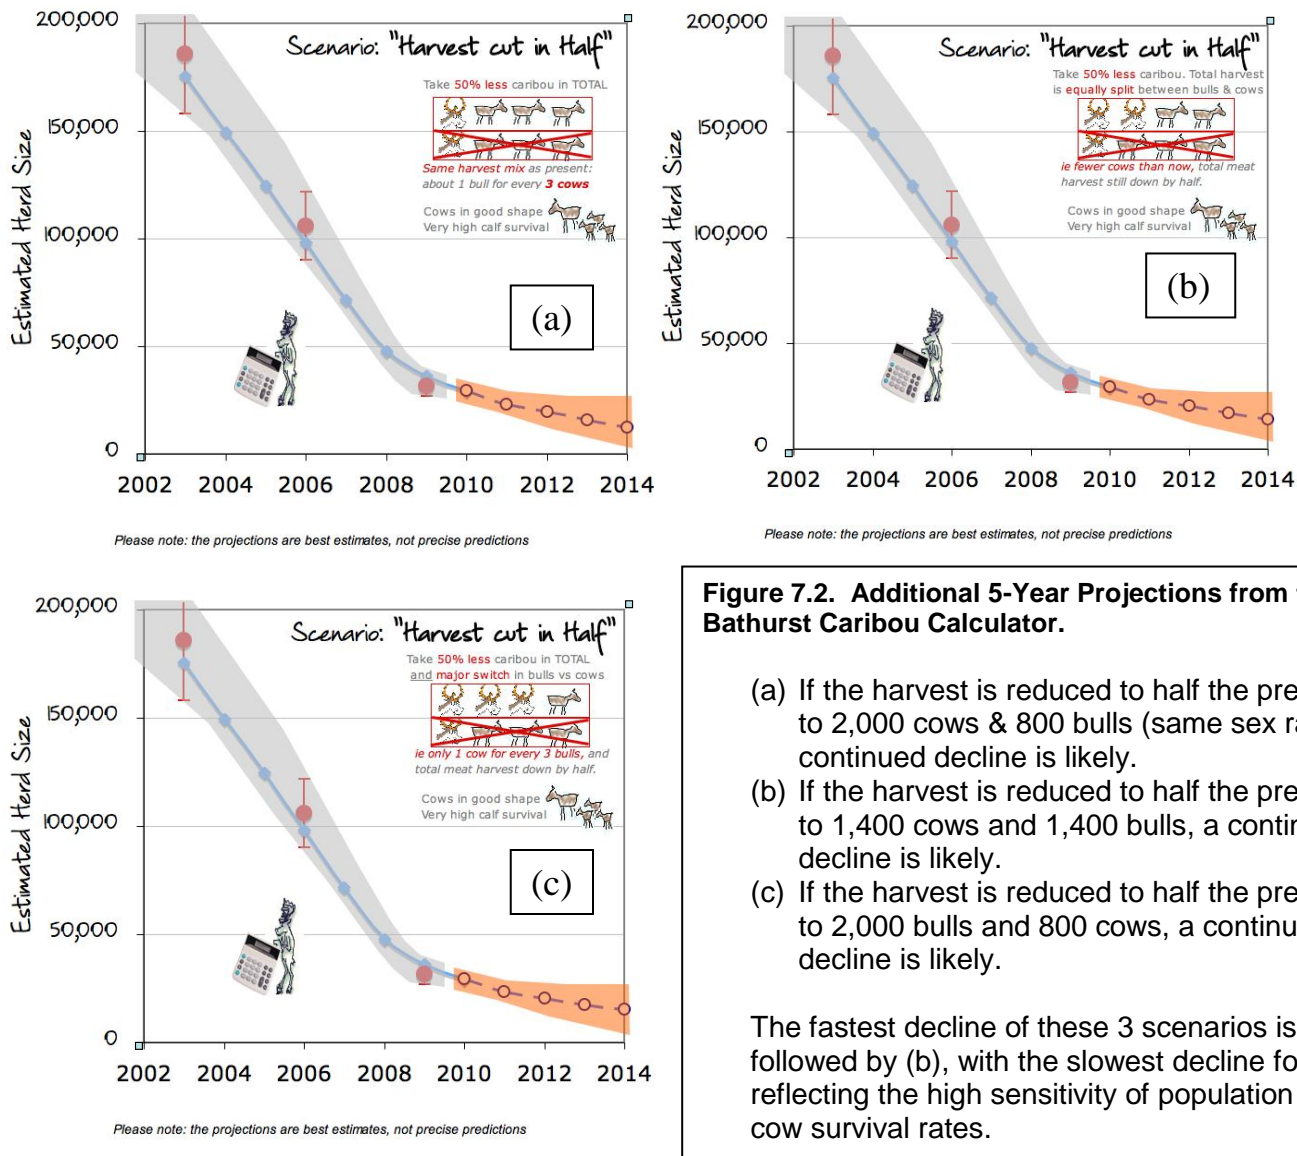

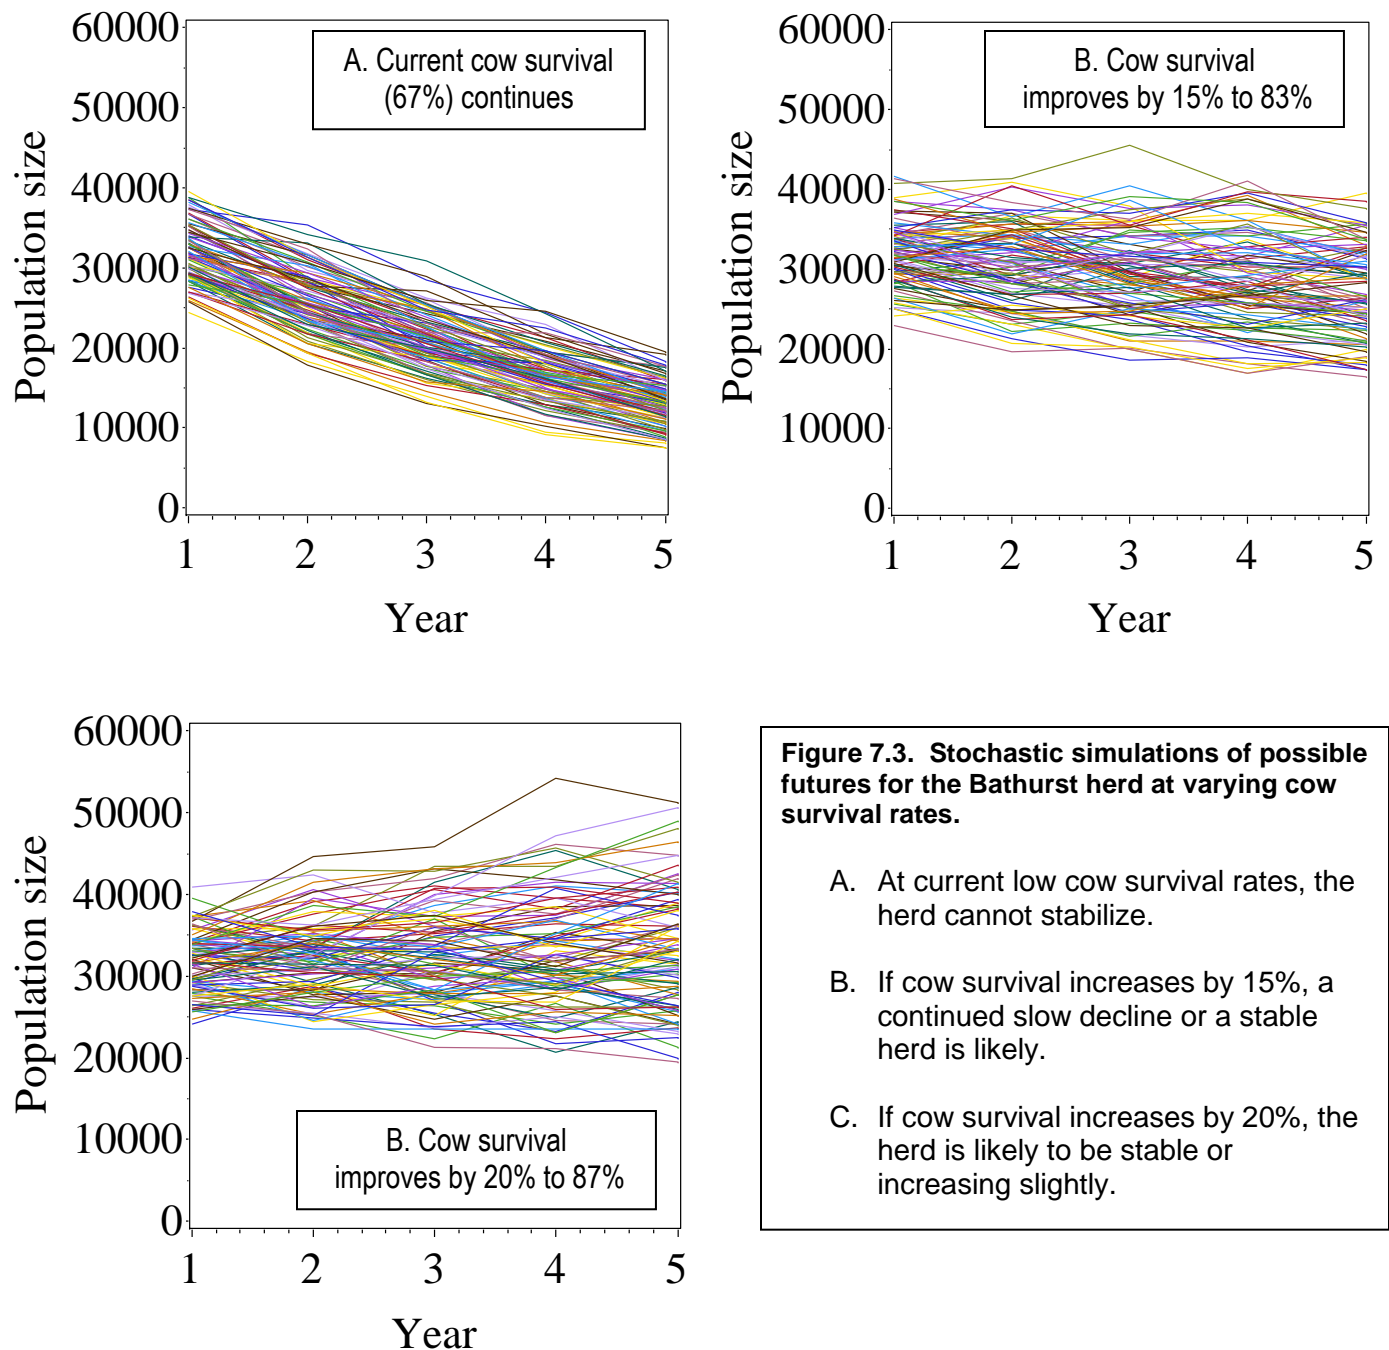

Figure 7.1. 5-Year projections from the Bathurst Caribou Calculator

The model projections in Figure 7.2 all use a reduced harvest of 2800 caribou, about half an estimated total for the Bathurst herd in recent years of 4000 cows and 1600 bulls. The sex ratio was varied from 71% cows to 50% cows and 29% cows, with the same total harvest taken. In each case, the projected population trend is toward a continued decline at a slower rate. Of the 3 sex ratios, the fastest decline would be for 71% cows and the slowest for 29% cows, again confirming the importance of the cow harvest to population trend.

7.2 Stochastic simulations for the Bathurst herd

Boulanger et al. (2009) used a stochastic demographic model to estimate demographic parameter values that were needed for the Bathurst herd to recover. The stochastic model was similar to the OLS model and the Caribou Calculator used for model fitting as described in previous sections except that it also simulated variance in demographic parameters. Parameters such as adult survival and calf survival vary by individual caribou, and vary temporally. It is essential that this variation, which can affect overall herd growth, is considered when evaluating scenarios for herd recovery. Estimates of variance from field-based measurement contain both sampling and biological or process variance. For demographic modeling, process or biological variation in parameters is most useful (White 2000). Boulanger et al. (2009) first used a variety of statistical methods to separate process from the sampling variance in estimates.

They then ran sets of simulations in which the model was run many times with variation simulated in all demographic parameters. This generated unique yearly population sizes for each run as illustrated in Figure 7.3.

Boulanger et al. (2009) simulated a range of values for adult female survival rate, calf survival rate, and fecundity as suggested by the OLS model exercise, and then ran simulations of population growth with variance in each parameter simulated. The geometric mean of successive change in population size, termed λ , was then estimated to determine what range of parameters was needed for the population to recover. A λ of 1 would mean that the population in a given year was similar to the population in the previous year, implying stability. A λ value less than 1 would imply the population is decreasing whereas a λ greater than 1 would imply the population is increasing. The female segment was simulated for this exercise.

It should be noted that the simulations shown vary some parameters but leave cow survival as unchanged. A cow survival rate of 67% would assume that the harvest of cows would decrease as the number of cows got smaller. If the cow harvest remains at a constant level (as in the Caribou Calculator projections), cow survival would continue to decline, and these projections would then produce similar results to the Caribou Calculator projections.

Figure 7.4. Projected Bathurst population trend (lambda) with various combinations of calf survival and cow survival, at low or high fecundity.

Results from simulations suggested that the herd would continue to decline unless calf survival was greater than 0.3 regardless of increases in adult female survival (Figure 7.4). An increase in adult female survival to 0.86 (which is the estimated 1985 level) would allow the herd to stabilize with calf survival levels of 0.53 (low F_a) to 0.50 (high F_a). An increase in adult female survival to 0.91 would allow the herd to stabilize with calf survival values of 0.32 (high F_a) to 0.35 (low F_a). The parameter levels required for recovery are similar to those observed in the Western Arctic herd (Haskell and Ballard 2007) and the Porcupine herd (Fancy et al. 1994, Walsh et al. 1995).

7.3 Risks associated with a strongly skewed sex ratio (few males)

The sensitivity of population trend to small changes in barren-ground caribou cow survival rates (Porcupine herd: Fancy et al. 1994, George River herd: Crete et al. 1996, Bathurst herd: this report) is well established. Management of the Bathurst herd will need to result in substantially higher cow survival rates if the herd is to have any chance of recovering. However, a heavy harvest of males may lead to a highly skewed sex ratio (low bull:cow ratio) and this strategy, if taken to extremes, may also have negative implications for the Bathurst herd. As reviewed earlier, bull:cow ratios in the Bathurst herd have been the lowest (2006-2008) of the herds ENR monitors. We review some studies on the effects of a male-biased hunter harvest in this section.

Caribou and reindeer are gregarious and during the breeding season, prime bulls often have harems of a dozen or more females, and the prime bulls will attempt to breed as many of these females as possible (Bergerud 1974). Present-day (2009) reindeer herders in Alaska maintain 1 bull for every 15-20 females (5-7 bulls: 100 cows), as their experience has been that this is sufficient to breed all the females (G. Finstad, University of Alaska, pers. comm. 2009). In moose, which are much less gregarious and where cows might

conceivably not find a bull if bulls are very scarce, a change from 16 bulls: 100 cows to 29 bulls: 100 cows in a heavily hunted population had no effect on calf:cow ratios, (normal) pregnancy rates, or sex ratio of calves in Alaska (Schwartz et al. 1992). In an experimental study with reindeer, a strongly skewed sex ratio of 8-14 bulls: 100 cows did not affect calving rate (Holand et al. 2003). Bergerud (1974) felt that at a sex ratio of 1 bull to 12 cows (8 bulls:100 cows), there might not be enough bulls to breed all the cows in Newfoundland caribou. It is clearly possible for one caribou or reindeer bull to breed several females, and a sex ratio somewhat skewed toward low bull:cow ratios is not likely to affect pregnancy rate. However, there are reasons to be cautious about skewing a caribou herd's sex ratio heavily toward females, particularly if it persists for an extended period.

Recent experience with other polygamous large herbivores suggests the need for caution when the sex ratio becomes skewed strongly to females (Langvatn and Loison 1999, Mysterud et al. 2002, Hard et al. 2006). The mechanisms for population declines in other species with a sex ratio strongly biased toward females include breeding by young bulls, which may cause delayed conception, later calving, lower birth weights and lower calf survival (Mysterud et al. 2002). Holand et al. (2003) used an experimental approach to investigate the consequences of a very skewed sex ratio (8-14 bulls:100 cows) in reindeer. Calving was later with the skewed ratio and the age of the bulls did not affect the date of calving, but calving rate (productivity) was not affected. Synchrony of births and calf birth weight increased with the higher sex ratio. Although the reindeer were in a large enclosure, the number of animals was low which suggests caution in extrapolating these results to free-ranging caribou. Coltman et al (2004) showed that over a 30-year period, harvest of about 40% of a bighorn population's large rams affected the herd's genetics and there was a tendency toward smaller horns in males. Hard et al. (2006) suggested a minimum sex ratio of 18 males:100 females in red deer to avoid negative genetic effects of a very skewed sex ratio and to ensure that a sufficient number of large older males survived the breeding season. This echoes concerns that have been raised in NWT communities about heavy harvest of prime bulls and the potential impacts to the herd's health and genetics, as well as the role of prime bulls in the southward migration to wintering grounds.

Although this is not an exhaustive review of the subject, caution should be used in considering harvest management for the Bathurst and other caribou herds. The Bathurst herd's sex ratio in recent years has been lower than in other NWT herds, which may in part reflect harvest pressure on this herd. Leaving a healthy number of prime bulls to breed the cows should be an objective of management, even if the highest priority should be to increase Bathurst cow survival, without which the herd cannot recover.

7.4. Conclusion

The data and modeling presented in this report are not as complete as we would like, but there is little doubt among the authors that the decline of the Bathurst herd from 2006 to 2009 is real and that the herd cannot recover unless cow survival rates increase substantially in the near future, along with continued good calf survival and high pregnancy rates. Barren-ground caribou herds have most likely varied widely in numbers for hundreds and perhaps thousands of years, and a large part of the Bathurst decline since 1986 is likely due to weather-related effects such as years with a late spring or poor summer vegetation growth. The Bathurst herd would most likely have declined between 2000 and 2006 due to these kinds of environmental factors. The high pregnancy rates, good condition in cows, and increased calf:cow ratios from 2007 to 2009 suggest that the herd is experiencing better environmental conditions and might stabilize or begin to increase if cow survival rates improve. However, many factors outside human control will continue to affect the herd, and the best harvest management (closure) can only provide the herd with an opportunity to recover.

We would also underscore the importance of not allowing the Bathurst herd to fall to very low numbers, as has happened to the Beverly herd recently and to the Fortymile herd in the past. At very low numbers, barren-ground caribou have a fundamentally different relationship with predators, and several barren-ground caribou herds (George River, Fortymile, Mulchatna) that fell to very low numbers spent extended periods at low numbers, in some cases decades, before increasing again. At very low numbers, Beverly caribou cows

have had very low adult survival and very low calf survival, and some of the cows have moved to the Ahiak herd's calving grounds. They no longer have the advantage of swamping predators by calving in large numbers in an area with few predators, the strategy that allows barren-ground caribou to reach numbers beyond the capacity of predators to limit. The likelihood of unpredictable and perhaps uncontrollable changes in barren-ground caribou behaviour and predator-prey ecology increases as a caribou herd reaches very low numbers.

9.0. Appendix 1. Detailed Information for June 2009 Bathurst Calving-Ground Photo Survey

Appendix 1A. Field team involved in June 2009 Bathurst Calving Ground Survey

Team Member	Role	Affiliation
Jan Adamczewski (JA)	Biologist	Government of the Northwest Territories
Jennifer Bailey (JB)	GIS Technician	Government of the Northwest Territories
John Boulanger (JB)	Biometrician	Integrated Ecological Research
Steve Blanchette (SB)	Pilot (Turbo Beaver C-FOPE)	Air Tindi
Adam Bourque (AB)	Pilot (Cessna Caravan C-GATY)	Air Tindi
Frank Camsel (FC)	Observer & Community Representative	Tlicho Government
Karin Clark (KC)	Biologist	Wek'èezhii Renewable Resources Board
Bruno Croft (BC)	Biologist	Government of the Northwest Territories
Noel Doctor (NC)	Observer & Community Representative	Yellowknife Dene First Nation
Doug Evans (DE)	Photographer (Challenger C-GEOS)	Geographic Air Survey Ltd.
Ron Fatt (RF)	Observer & Community Representative	Lutsel K'e Wildlife Lands & Environment Department
Wally Feisal (WF)	Pilot (Challenger C-GEOS)	Geographic Air Survey Ltd.
Alicia Kelly (AK)	Biologist	Government of the Northwest Territories
Lee ???	Pilot (A-Star G-ABX)	Great Slave Helicopters
George Mandeville (GM)	Observer & Community Representative	North Slave Metis Alliance
John Nishi (JN)	Biologist	EcoBorealis Consulting Inc.

Appendix 1B. Number of 1+-year-old caribou observed during a photographic transect survey of a high density stratum, Bathurst calving ground, 8 June 2009

Update Appendices

High Density Photographic Stratum

Transect No.	Transect Length (km)	Transect Area (km ²)	1+ yr-old Caribou Counted
1	43.55	39.82	71
2	43.55	39.82	39
3	43.50	39.78	51
4	43.45	39.73	51
5	54.49	49.82	81
6	54.49	49.82	79
7	54.49	49.82	158
8	54.49	49.82	130
9	54.49	49.82	192
10	54.49	49.82	391
11	54.49	49.82	220
12	54.49	49.82	580

$$\hat{\theta}_i = nS - (n-1) St$$

Where:

$\hat{\theta}_i$ = Pseudovalue for jackknife estimate

n = Original sample size

S = Original statistical estimate

St = Statistical estimate when original value i has been discarded from sample

i = Sample number (1,2,3,..., n)
